ACKNOWLEDGEMENT

I would like to express my gratitude to my advisor, Dr. Catherine Macris, for her guidance and patience throughout the entirety of this research. Her constant support proved invaluable, for which I am forever grateful. I also extend special thanks to my committee members, Dr. Andrew Barth and Dr. Kathy Licht, for their unyielding guidance and encouragement, both with my research and during my time at IUPUI.

Thank you to the National Science Foundation, whose funding has made this research possible (NSF-EAR Grant 1664553). I would like to thank Dr. Susannah Dorfman and Alison Farmer at Michigan State University for conducting the electron probe microanalysis of the Fe-bearing samples, as well as Dr. Dorfman's guidance, advice, and use of the samples this research produced.

I am thankful to Craig Lundstrom at the University of Illinois Urbana-Champaign for both his instruction and allowing me the use of the scanning electron microscope. I would also like to thank Rick Weber, Anthony Tamalonis, and Oliver Alderman of Materials Development, Inc. for their support and advice concerning the operation of the aerodynamic levitation laser furnace, which was integral to the success of this research.

I am grateful for the unyielding support and encouragement of my family. I give special thanks to John Shukle for his friendship, as well as coding and coffee breaks along the way. Working together on Shiny applications and coding projects has been a fantastic experience so far, and will continue to be for years to come.

This research would have been impossible without the support of the IUPUI Graduate School and the IUPUI Department of Earth Sciences, and I express my gratitude to those agencies.

Preface

The following work is separated into two main sections, both of which aim to improve upon the current state of methods and available tools for their respective applications. The first chapter addresses the development of a specific methodology, finessed over the course of many iterations, each of which is described in detail. This methodology details the synthesis of glasses with the chemical compositions of the main minerals in the mantle: $(\text{Mg, Fe})_2\text{SiO}_4$ (olivine) and $(\text{Mg, Fe})\text{SiO}_3$ (pyroxene). This process ensures the production of compositionally accurate and homogeneous glasses using an aerodynamic levitation laser furnace. These glasses will act as lower mantle environment proxies used in high pressure experiments.

The second chapter details the creation of two different web applications, coded in the programming language R. The first application, LaserPlot, takes the output file from the aerodynamic levitation laser furnace and distills vital information, runs calculations, creates informative plots, and outputs a table of useful information and plots which enhance the efficiency and accuracy of data synthesis and regression for levitation experiments. The second application, RockR, is a collaborative project between myself, John Shukle, and Jeremiah Mickey. It was built as a teaching tool that enables the plotting of data onto a wide variety of pre-rendered classification and discrimination diagrams, which are commonly used in the geosciences. Although these plots are widely used, their free availability is limited. RockR addresses these issues, aiming to improve upon the available solutions, designed in a classroom-friendly manner that includes links to relevant literature and

explanations of plot types with the intent to improve understanding as well as functionality.

These three projects – the glass synthesis methodology, LaserPlot, and RockR – all complement each other, such that LaserPlot and RockR both enhance the methodology by distilling and detailing sample levitation conditions and facilitating the graphical representation of the semi-quantitative and quantitative compositional analyses. The tabular output file produced from each levitation experiment can be analyzed by LaserPlot, which calculates and collects important characteristics of each levitation experiment. The ternary and bivariate plotting capabilities of RockR allow for simple and streamlined plotting processes. The bivariate diagrams are used to display the Mg-pyroxene and Mg-olivine compositions, which contain SiO_2 and MgO components. The ternary diagrams enable the plotting of the Fe-bearing pyroxenes, which contain SiO_2 , MgO , and Fe_2O_3 components.

DEVELOPING LEVITATION LASER-FUSED GLASSES AS PROXIES FOR LOWER
MANTLE EXPERIMENTS: A METHODOLOGICAL APPROACH

Observations of heterogeneities in Earth's mantle motivate studies of mantle phase assemblages with variable composition. As samples cannot be directly collected from these regions, synthetic glasses can act as analogues for mantle melt and starting materials for high-pressure synthesis of stable mantle minerals in experiments. Here, I develop a specific methodology to produce homogeneous glasses that accurately span the composition space from enstatite (MgSiO_3) to forsterite (Mg_2SiO_4), as well as Fe-bearing enstatite ($(\text{Mg}_{0.1}\text{Fe}_{0.9})\text{SiO}_3$ and $(\text{Mg}_{0.95}\text{Fe}_{0.05})(\text{Si}_{0.95}\text{Fe}_{0.05})\text{O}_3$) with variable oxidation states. This study systematically tests and iterates upon glass synthesis methods using an aerodynamic levitation laser furnace, in which a spherical glass sample levitates on a gas stream flowing vertically through a conical nozzle, while being heated from above with a 400 W CO_2 laser. With sample diameters of 0.6-2.0 mm, shutting off the laser results in supercooling of levitated spheres at rates between 350 and 1350 $^\circ\text{C/s}$. Sample preparation begins with grinding and mixing pure oxide powders in an agate mortar and pestle, followed by heating in a high temperature oven to devolatilize the mixture. Powders (0.5-7 mg aliquots) are fused into spheres in a copper hearth plate. To tune Fe valency and vitrify each sphere, samples are then levitated on flows of Ar, O_2 , 5% CO in Ar, 5% CO_2 in Ar, or combinations of two of these gases, while being heated with the laser to temperatures above the liquidus for each composition for ~ 10 s before quenching. After x-ray diffraction (XRD)

analyses confirm vitrification, a dual polish is applied, exposing parallel flat polished surfaces for scanning electron microscope (SEM) and electron probe microanalyzer analyses (EPMA). Back-scattered electron images and energy-dispersive x-ray spectroscopy (EDS) analyses of the spheres are obtained first on the SEM to gauge compositional accuracy and homogeneity, then EPMA analyses determine quantitatively the samples' compositions. Once fully characterized, these glasses can be used in diamond anvil cell experiments, where they can act as proxies for an otherwise inaccessible area of the Earth. In addition to the development of this methodology, two web applications produced during this research aid in visualization of both data logs and analytical results.

Chapter 1: Laser-Fused Levitation Glasses

1.1 Introduction

Deep Earth seismic wave speed variations have shown heterogeneities in the mantle, specifically near the core-mantle boundary (CMB), likely due to either compositional differences or to phase changes (Auzende et al., 2008; Lee et al., 2004; Lee et al., 2008; Murakami and Bass, 2011; Williams and Garnero, 1996).

$(\text{Mg,Fe})_2\text{SiO}_4$ (olivine) and $(\text{Mg,Fe})\text{SiO}_3$ (pyroxene) compositions constitute approximately 85% of the upper mantle and their high pressure equivalents are believed to make up the majority of the lower mantle (Anderson, 1977).

Experimental petrologists and mineral physicists working on problems in the deep Earth use these compositions for starting materials in multi-anvil and diamond-anvil cell experiments, which can reproduce pressures and temperatures equivalent to those in the lower mantle.

1.1.1 Objective

The goal of this research is to develop a specific methodology, which consistently produces homogenous glasses with the chemical compositions of the minerals enstatite (MgSiO_3), forsterite (Mg_2SiO_4), and Fe-bearing enstatites ($(\text{Mg}_{0.9}^{\text{II}}\text{Fe}_{0.1})\text{SiO}_3$ and $(\text{Mg}_{0.95}^{\text{III}}\text{Fe}_{0.05})(\text{Si}_{0.95}^{\text{III}}\text{Fe}_{0.05})\text{O}_3$). Glasses, rather than their crystalline counterparts, are desirable as starting materials for high pressure experiments because they maintain compositional homogeneity to a micron scale, and are easily converted to high-pressure minerals assemblages in the diamond anvil cell. By establishing a reliable and repeatable method of making these glasses,

deep Earth petrologists and geophysicists can have consistent starting materials to use in these high-pressure experiments, where they can test various theories about deep mantle processes, conditions, and materials.

1.1.2 Background

The process of creating glasses of known composition begins with oxide powders, which are fused by low-power laser heating into mm-sized spheres. These spheres are levitated in gas flows, heated above their liquidus, and cooled at fast rates to vitrify rather than crystallize the final products. Some background information is necessary in order to understand the transition between molten material and glasses versus molten material and crystalline solids. Melts can be categorized according to their 'strength.' The strength of a melt is a relative measurement of the rate of structural relaxation within the glass transition. The glass transition represents a range of temperatures during which a liquid-like structure changes to a solid-like structure or vice versa and structural relaxation theory concerns the relaxation state of the medium through this transition (Calas et al., 2006; Dingwell and Webb, 1990; Dingwell, 2006,; Moynihan et al., 1974; Mysen and Richet, 2005).

Liquid and glassy states are defined as relaxed and unrelaxed, respectively. At temperatures above the glass transition, the relaxed liquid is in equilibrium. Within the glass transition, the fluid falls out of equilibrium and achieves a partially-relaxed state. The end of the glass transition, and the beginning of the glassy state, is marked by the temperature at which the rate of structural relaxation change slows to the

degree that it effectively ceases to change on an experimental time scale (Henderson et al., 2006; Moynihan et al., 1974). The internal structure of the resultant glass mirrors that of the melt at the fictive temperature (T_f), which represents the temperature at which the melt was last in equilibrium or the instant before the melt entered the glass transition. This temperature is directly affected by the rate at which the melt cools, where slower cooling rates result in lower T_f and faster cooling rates result in higher T_f . The more gradual the cooling rates are, the more time is allowed for the melt to adjust and maintain equilibrium as cooling progresses (Calas et al., 2006; Moynihan et al., 1974).

Melts with very gradual structural relaxation changes over the course of large glass transition temperature ranges are characterized as “strong” melts, while melts with more abrupt changes in structural relaxation over the course of small glass transitions are characterized as “fragile” or “weak” melts (Tangeman et al., 2001; Kohara et al., 2004). As the temperature decreases, the internal structure is constantly rearranging itself, trying to maintain equilibrium. T_f is reached when the kinetics of the structure are no longer able to keep up with the cooling rate. The stronger melts show more gradual changes in viscosity, and T_f can be achieved at lower temperatures. Fragile melts, on the other hand, present with much faster changes in viscosity and require higher cooling rates to keep them from maintaining equilibrium, which would result in them crystallizing (devitrifying) rather than cooling to an amorphous glass (vitrifying) (Stebbins, 2016). When fragile melts are cooled at slower rates, the internal structure becomes more ordered very quickly (Fig. 1). When the structure snaps into place and crystallization is achieved, a

process called recalescence occurs, which is the release of the latent heat of crystallization when a melt becomes a crystalline solid in the glass transition (Debenedetti & Stillinger, 2001; Miura et al., 2010; Miura et al., 2011; Moynihan, 1995; Nagashima et al., 2006; Nagashima et al., 2008; Tangeman et al., 2001; Webb, 1997; Weber & Benmore, 2017). Recalescence is the primary barrier to fragile melt vitrification, avoided by achieving fast enough cooling rates, relative to the glass transition temperature range.

1.1.3 Oxygen Fugacity

The availability of free oxygen in a system is the driving factor for valency. For this research, the availability of oxygen is particularly important with respect to iron, which is the 4th most common element in the Earth's crust and occurs naturally in 3 different oxidation states: Fe⁰, Fe²⁺, and Fe³⁺ (Frost, 1991). At atmospheric pressure and assuming ideal gas behavior, this unit can be measured as the partial pressure of oxygen (x_{O_2}). However, when considering geologic applications and investigating systems with pressures much greater than 1 bar, x_{O_2} is no longer an accurate assessment of the oxygen availability. For such conditions, oxygen fugacity (f_{O_2}) is considered. The f_{O_2} variable is a unit of pressure and is often used with reference to buffers, which are represented as curves that highlight temperature-dependent f_{O_2} values where specific minerals are stable in natural systems (Fig. 2). With respect to temperature, lower f_{O_2} correlates with reducing Fe conditions and higher with oxidizing Fe conditions, while the lowest f_{O_2} encourages the production of metallic Fe (Frost, 1991; Johannes and Holtz, 1996).

When conducting experiments synthesizing materials, f_{O_2} can be controlled within a high temperature environment at atmospheric pressure. This method was developed in 1945 by Darken and Gurry and is commonly used for iron-bearing systems. Gases like CO/CO₂ or H₂/CO₂ are mixed in specific ratios and, as the experiment occurs at atmospheric pressures and high temperatures, the partial pressures are interchangeable with f_{O_2} (Holloway and Wood, 1988). As a result, the partial pressures can be controlled by the gas flow rates of the individual gases in the mix.

1.1.4 Previous Research

Prior to the use of aerodynamic levitation techniques, glass synthesis methods utilized platinum wire loops or alumina, platinum, or graphite containers to support samples, and have had three main issues (Fig. 3). First, this process caused contamination of the sample, as iron oxide reacted with the container or wire support. The result was iron and oxygen leaching from the sample and altering its intended composition (Grove, 1981; Holloway and Wood, 1988; Merrill and Wyllie, 1973; Pack et al., 2010; Roskosz et al., 2006). Second, this container problem restricted the rates of supercooling, which resulted in devitrification of weak or fragile melts like forsterite (Weber et al., 1993; Weber, 2010; Benmore and Weber, 2017). The third main issue was that contact points between the sample and the container/wire became nucleation points, which resulted in radial fan-shaped crystallization patterns extending outward (Nagashima et al., 2006).

After the development of the aerodynamic levitation laser furnace by D. A. Winborne and P. C. Nordine (Winborne et al., 1976) came the additional development of the conical nozzle laser (CNL) (Coutures et al., 1990) (the components of the model used in this research will be discussed in detail in section 1.2.2). The instrument was used primarily for materials development interests (e.g. aluminum oxides, ceramic superconductors, and reflective glass coatings) (Weber et al., 1994; Weber et al., 2002; Weber, 2010), in-situ melt structural analyses using noncontact diagnostic instruments (e.g. nuclear magnetic resonance spectroscopy (NMR), x-ray diffraction (XRD), x-ray absorption near-edge structure spectroscopy (XANES), and neutron diffraction) (Alderman et al., 2017b; Mathiak et al., 2005; Poe et al., 1992; Weber et al., 2014), chondrite and chondrule synthesis (Miura et al., 2010; Miura et al., 2011; Nagashima et al., 2006; Nagashima et al., 2008; Pack et al., 2010), and silicate glasses (Alderman et al., 2017b; Tangeman, et al., 2001; Weber et al., 2014; Wilding et al., 2004).

1.2 Methods

1.2.1 Overview

The methods section begins with a detailed description of the parts of the laser used in this research. The section continues to detail the individual steps of the glass synthesis and analysis methodology, the creation and subsequent testing of which is the primary focus of this research. Each step lead to the formation of glass spheres with specific chemical compositions. The following sections will provide a thorough explanation of the individual steps needed to begin with pure oxide powders and

end with analyzing glass samples. The glass synthesis methodology began with stock solution oxide powders, which were weighed out in stoichiometrically-determined ratios, ground down to the point that all the individual powder grains are approximately the same size, and baked (heated in a high temperature oven) to remove volatiles from the mixture.

The mixture was then portioned out into concave depressions of a copper hearth plate and heated with a laser at low power until the powder grains fused together into spheres. These spheres were levitated on gas flows and heated with the same laser to temperatures above their liquidus, and were then cooled by turning off the laser. Due to their small volumes and surface areas, the samples (mostly) supercooled and vitrified rather than crystallizing. After vitrification, parallel surfaces of the glasses were ground down to expose the interior of the spheres. The upper surface was polished to a grit size of 0.25 μm , which is optimal for semi-quantitative and quantitative analyses. XRD analyses were used to determine whether a sample was amorphous or crystalline. Semi-quantitative scanning electron microscopy (SEM) combined with energy dispersive x-ray spectroscopy (EDS) analyses were used to quantify the elemental ratios within a given area on a sample and quantitative electron probe micro-analysis (EPMA) analyses were used to do the same analysis as the SEM, but to a higher degree of accuracy and precision.

1.2.2 Aerodynamic Levitation Laser Furnace

To fully understand the processing steps of the methodology, it is important to have a detailed description of each part of the aerodynamic levitation laser furnace,

which is the primary instrument used in this glass synthesis research. The individual parts of this assemblage include: laser (Fig. 4 A), laser hearth (Fig. 5), levitation chamber (Fig. 4 B), gas mixing valves (Fig. 4 C), optical pyrometer (Fig. 4 D), and video camera (Fig. 4 E).

1.2.2.1 Laser

This system uses a Synrad i401 400 Watt continuous-wave CO₂ laser, which is an embedded class 4 laser that is configured for class 1 laser operation (Fig. 4 A). The laser beam alignment is controlled by molybdenum mirrors, which result in the beam being directed vertically down into either the laser hearth or levitation chamber and a low-power visible laser parallels this path for user tracing and alignment control during use. Adjustable focusing optics allow for different laser power densities to be directed at the sample, in addition to the laser power controlled by the user within the operational software.

1.2.2.2 Laser Hearth

The laser hearth is a chamber which is enclosed on all sides, except for a circular opening in the front and two horizontal slits opposite each other and adjacent to the opening at the front (Fig. 5). The opening at the front has a glass piece which fits onto the outside, resting on the two screws jutting outward near the base. Placement of this glass piece closes an interlock switch, which is part of the safety fault system for the laser. The slits on either side of the chamber allow two hearth rods to extend outward from a copper hearth plate (containing sample powders)

(Fig. 6) within the center of the chamber. The hearth rods give the user control of the placement of the hearth plate within the chamber while the laser is in use and a guide tracer beam, similar to what is used in laser pointers (section 1.2.2.1), shows the user where the CO₂ laser beam will strike the plate so that the user can know where the heating will begin and can move the hearth plate accordingly.

1.2.2.3 Levitation Chamber

The levitation chamber is constructed out of vacuum-grade non-magnetic steel and is an interlocked chamber, within which the user can control the atmosphere via the gas mixing valves (described in section 1.2.2.4) that pass up and through an aluminum alloy conical nozzle in the center of the chamber (Fig. 7). The chamber has six potential openings, each of which is manually sealed with either glass lenses and clamps or non-magnetic steel covers and clamps. Two of the openings extending perpendicularly from the chamber to the left and right (Figs. 4 B and 7) have 25 mm ports and could be used for external instrumentation, but neither was used at any point in this research. The two openings extending horizontally and adjacent to the 25 mm ports – facing the user and extending away from the user – have 50 mm ports. The port extending away from the user remained sealed and unused throughout this research. The port facing the user has a glass lens covering it when closed, and is the window through which the levitation experiments are viewed (through welder's glass to protect the users' eyes). When open, this port is used to insert and remove samples for the levitation experiments. The two openings directed at 45° angles to the left and right from the chamber have glass lens

covering the openings and act as windows for the optical pyrometer (section 1.2.2.5; Fig. 4 D) and video camera (1.2.2.6; Fig. 4 E).

1.2.2.4 Gas Mixing Valves

The graphical user interface allows for control over the ratio between two gas compositions (Fig. 8 A), and the flow rate to be channeled upward vertically through an aluminum alloy divergent conical nozzle, which can be seen inside the chamber in Fig. 7. Two gas inputs come through the individual gas mixing valves, before joining and directing a single gas flow mixture (Figs. 4 C and 8 B) through the conical nozzle.

1.2.2.5 Optical Pyrometer

The sample temperature during laser heated experiments is measured using an integrated Chino IR-CAS near-infrared optical pyrometer with a close-up lens attachment. This is directed at the sample location through the left 45° angle port of the levitation chamber (Figs. 4 D and 9). The device has a field of view of 0.6 mm, requiring it to be manually adjusted to be aimed at the sample prior to levitation experiments.

1.2.2.6 Video Camera

The video camera is a digital Point Grey camera, which is directed at the sample location through the right 45° angle port of the levitation chamber (Figs. 4 B and 10). The camera allows the user to view the sample during levitation. As the

temperature of the sample increases and the emitted light becomes more intense, the camera automatically adjusts the exposure and maintains sample visibility.

1.2.3 Powder Preparation

The first step in the process of synthesizing glasses with the chemical compositions of the mantle's chief constituents is powder preparation. In this study, this was achieved by combining predetermined ratios of high-purity oxide powders, such that the mixture was equivalent to the intended composition of the glass (Edgar, 1973; Holloway and Wood, 1988). Puratronic stock solution powders of SiO_2 , MgO , Fe_2O_3 , and ^{57}Fe doped Fe_2O_3 with respective purities of 99.995%, 99.995%, and 99.998%, were weighed out in stoichiometric ratios to recreate the desired minerals' formulas (Table 1).

Each individual powder was ground under acetone in an agate mortar and pestle using irregular and non-repeated patterns when moving the pestle (Holloway and Wood, 1988). The solution was ground into a slurry and grinding continued until all the acetone evaporated. The dry powder was then scraped back together and the process was repeated. The time from when the acetone was added and grinding commenced until all the acetone evaporated will henceforth be called one session. Each stock solution was ground for three sessions of 20 minutes, then the powders were combined, and the solution was ground for one session of 20 minutes. The resulting powder was baked in a high temperature oven to fully dehydrate/devolatilize the mixture. The oven temperature increased at $100\text{ }^\circ\text{C}/\text{hour}$ until 800°C was reached, where it remained constant for 1 hour. The powder was

then stored in a desiccator to minimize absorption of water vapor from the air (Edgar, 1973).

1.2.4 Laser Fusing

The powder mixture must be fused into spheres, in order to be capable of levitating within a concentrated vertical gas flow. In section 1.3.2, the evolution of this portion of the methodology will be expanded upon. The process began with 0.5-7.0 mg aliquots of sample powder, which were each placed in one of the twelve evenly-dispersed concave depressions of a copper hearth plate (Fig. 6). This plate was then positioned within the aerodynamic levitation laser furnace's laser hearth (described in section 1.2.2.2; shown in Fig. 5). Two small rods attached to opposite sides of the hearth plate allowed the user to move the plate during the fusing process.

The powder in each depression on the hearth plate was heated with the laser at power levels of 9% to 9.5% (corresponding temperatures could not be recorded within the hearth chamber) for ~10 second intervals, while the plate was moved in small circles to facilitate formation of spheres from the powder mixture. Laser power levels of 10.5 or higher resulted in loss of sample material through vapor being release from the sample surface, while laser powers of 8.5 or lower either left the powder unaltered or merely singed it. As the powder fused together, the concavity of the depression and the movement pattern caused the hardened, fused portions to fall onto the remnant powder. This process transformed the loose

powder mixture into approximately spherical samples. Fused sphere diameters were measured with calipers to a precision of 10 microns (Table 2).

1.2.5 Levitation

The next step involved the levitation and vitrification of the fused spheres using appropriate gas compositions and temperatures. The spheres were vitrified using the levitation chamber (described in section 1.2.2.3) of the aerodynamic levitation laser furnace (Fig. 4 B). Samples were levitated on flows of Ar, O₂, 5% CO in Ar, 5% CO₂ in Ar, or combinations of two of these gases (Figs. 11 A), flowing upward through a conical nozzle (Figs. 11 B and 11 C). While being levitated and enveloped by these flowing gases, samples were heated with the laser (Figs. 11 D and 11 E) to temperatures above the liquidus (Figs. 12 A and 12 B) of each composition for approximately 10 second intervals. Quenching occurred by shutting off power to the laser which, due to the very small surface areas of the spheres, resulted in most of the samples supercooling and vitrifying rather than crystallizing (Fig. 12 C).

1.2.6 Polishing

After vitrifying the synthetic glasses, they needed to be ground down to expose the interior of the sphere, and polished to facilitate XRD, SEM, and EPMA compositional analyses, which required planar surfaces without marring or scratches. In order to achieve polished surfaces on these small spherical samples, a systematic process was developed. Details of the evolution of this process will be expanded upon in section 1.3.3, culminating in the process summarized here. Glass

spheres were adhered to carbon tape in an aluminum dish within the inner ring of a polytetrafluoroethylene washer (0.25" thick, 0.141" outer diameter, 0.062" inner diameter) (Fig. 13). The remaining vacant space around the sample was filled with Dentsply Caulk Orthodontist Powder. A single drop of Dentsply Caulk Orthodontist Resin was applied to the powder and left to sit for an hour, during which time the resin hardened and formed a temporary epoxy, holding the sample in place within the washer. Both sides of the washer/sample were ground down using silicon carbide CarbiMet abrasive pads of various grit-sizes. Following grinding to expose flat, parallel surfaces on two sides, the surfaces were polished on microcloths sprayed with diamond suspensions.

The initial grinding steps required the application of high purity deionized water to silicon carbide pads. Four abrasive pads with increasingly fine grit sizes of 240, 320, 600, and 800, and with respective approximate grain sizes of 52, 35, 15, and 13 microns were used. Between each of the abrasive pad grit sizes, the sample was sonicated in water to remove residual grit and was then dried using a compressed tetrafluoroethane gas duster spray. Smaller samples, where maintaining a controlled grip on the sample during the compressed air drying method was in question, were placed on chem wipes and allowed to dry on their own after sonicating.

Polishing steps used MetaDi Supreme polycrystalline diamond suspension grit sizes of 6 μm , 3 μm , 1 μm , and 0.25 μm . The diamond suspension solutions were each applied to separate microcloths. Of the two exposed flat surfaces on the spheres, one side received only a coarse polish of the 240 grit-sized abrasive, while

the other plane was polished with increasingly fine grit sizes culminating in 0.25 μm polycrystalline diamond suspension. As was the case with the silicon carbide pad steps, the washer/sample was sonicated in water between diamond suspension solution polishes to remove residual grit grains and debris.

After the final polish, samples were viewed with a stereoscopic binocular microscope to confirm clean, unscratched surfaces. The polished glasses were removed from the temporary epoxy by sonicating the washer/sample in acetone, which reacts with and dissolves the dental resin that was previously holding the sample within the bounds of the washer. Once free of the resin, samples were sonicated in isopropanol, as acetone residue can be a source of contamination in both SEM and EPMA.

1.2.7 X-Ray Diffraction

Two forsterite synthesis experiments yielded samples that presented with surface textural variations, giving a ‘crumpled’ appearance instead of smooth surfaces (Figs. 14 A and 14 B), which required XRD analyses to refute or confirm that the source of the difference was devitrification (growth of crystals upon cooling) (Edgar, 1973). This was achieved using a Bruker D8 Discover XRD. Using both Vantec and LynxEye detectors, XRD analyses identified the presence or absence of internal crystalline structures, represented in the form of Bragg’s peaks. The Vantec detector assesses a larger active area and analyzes the sample more quickly than the LynxEye detector, but the latter produces a more accurate analysis. XRD analyses were performed on glasses which showed both crumpled and smooth

surfaces. The amorphous structure of the glasses was confirmed by both the absence of identifiable Bragg's peaks and a very broad and shallow background, centered near the crystalline compositional equivalent 2θ distance (Fig. 15). XRD analyses were utilized to determine the relationships between amorphous state and smooth surfaces versus crystalline state and anomalous exterior textures.

1.2.8 Scanning Electron Microscopy

Compositional accuracy and homogeneity within each synthetic glass sample, and among samples of the same intended composition, were assessed by both backscatter electron detection (BSE) and EDS on a TESCAN VEGA3 SB SEM at the University of Illinois – Urbana-Champaign. Prior to analysis, a thin carbon layer was applied to the samples using carbon sputtering in a vacuum chamber to reduce charging by creating a conductive surface. BSE images showed compositional variations by contrast differences in grayscale images. EDS results were collected by point analysis, with 3-4 points per sample, approximately evenly spaced between the center and outer edge of each sample (Fig. 17). EDS results (Tables 3 and 4) were collected as oxide ratios, and instrumental accuracy was ensured using a Materials Research Lab block olivine standard.

1.2.9 Electron Probe Micro-Analysis

Using a Cameca SX100 EPMA from the University of Michigan, glass compositions were determined with greater accuracy than the SEM data. Si, Mg, and Fe contents were analyzed by wavelength dispersive spectroscopy (WDS). Element

counts were calibrated using synthetic standards of Al_2O_3 for O, FeSiO_3 for Si and Fe, and forsterite for Mg, with the Fe counts being collected on multiple spectrometers and aggregated.

1.3 Evolution of Methodology

This section will detail the various iterations of each step of the methodology outlined in section 1.2. Through the course of this research, a specific methodology was formed that consistently created compositionally accurate and homogeneous glasses. In order to finesse this process, the different steps underwent changes that ranged between subtle and significant. The following will describe the different attempts that were made, both successful and unsuccessful. These procedures shaped the evolution of the final methodology (section 1.2).

1.3.1 Powder Preparation

The powder preparation step laid the foundation for the research. It began with stock solution oxide powders (SiO_2 , MgO , and Fe_2O_3), each of which was a primary constituent of the mineral compositions for Mg_2SiO_4 (olivine) and $(\text{Mg}, \text{Fe})\text{SiO}_3$ (pyroxene). These powders were weighed in stoichiometric ratios according to their intended composition and the resulting mixture was used for each of the following steps of the methodology. There were three different methods used in the evolution of the powder preparation step: A, B, and C. Each of these steps will be described below.

1.3.1.1 Method A

The first mixing method used a twist action shaker. This machine functioned in a manner similar to a ball mill, except that the shaking was less vigorous and the arm holding the container in place was fashioned as a pair of vice grips. This machine was used to mix the Puratronic powders of SiO₂, MgO, Fe₂O₃, and ⁵⁷Fe doped Fe₂O₃, held within sealed high-density polyethylene (HDPE) wide-mouth bottles (Alderman et al., 2017). Early attempts resulted in some of the powder sticking to the side of the container. Given that the MgO powder was a slightly finer grain size than the SiO₂ powder, it seemed plausible that this sticking would be counterproductive to the goal of thorough mixing. Using a ceramic ball inside the container resulted in material becoming packed against the sides and bottom of the container, rather than continually dislodging the material and reducing the grain size variation of the mixture. Special care and attention were put into keeping the individual stock solution powders from clumping together or to the sides of the HDPE wide-mouth bottles.

The twist action shaker mixing process was put through test runs, systematically altering duration, the angle at which the container was held, and the speed of the shaker, relative to full speed. The judgment of each scenario was whether it resulted in fine material sticking together on the side or bottom of the container. Operating the shaker at speeds above ½ speed always resulted in clumping, as did runs at ½ speed for durations above five minutes. Changing the angle of the container within the grasp of the shaker had no noticeable impact. Running the machine at ¼ speed resulted in less material sticking together, improving as duration increased. The

final settings – container held upright, twist action shaker operating at $\frac{1}{4}$ of the full potential speed, and durations varying between 1 $\frac{1}{2}$ minutes to 4 $\frac{1}{2}$ minutes – resulted in all the material remaining loose within the container, with no preferential clumping or sticking.

1.3.1.2 Method B

The next iteration of the mixing technique aimed to address the grain size variation, which was restricting thorough mixing of the Puratronic stock solution powders of SiO₂, MgO, Fe₂O₃, and ⁵⁷Fe doped Fe₂O₃. This consistent grain size reduction was accomplished by grinding under acetone for 10-minute sessions in an agate mortar and pestle. To reduce the SiO₂ grains to the size of the MgO and Fe₂O₃ grains, so the SiO₂ powder underwent two grinding sessions, followed by three grinding sessions of all the Puratronic powders mixed together (SiO₂ and MgO for enstatite and forsterite; SiO₂, MgO, and Fe₂O₃ for the Fe-bearing enstatites). The final mixture was then placed in a high temperature oven under the same conditions as in methods section 1.2.4.

1.3.1.3 Method C

This method of the powder preparation step represents the final and most successful method, which is why it is the same as what is outlined in the methods section 1.2.4.

The final iteration of the powder preparation step began with the same weighing of Puratronic stock solution powders of SiO₂, MgO, Fe₂O₃, and ⁵⁷Fe doped Fe₂O₃ with

respective purities of 99.995%, 99.995%, and 99.998%, based on stoichiometric ratios (Table 1). Each individual stock solution powder was ground under acetone in an agate mortar and pestle moving the pestle in non-repeated patterns (Holloway and Wood, 1988). The solution was ground into a slurry, continuing until all the acetone evaporated. The dry powder was then scraped back to the middle of the mortar and the process was repeated. The time from the addition of the acetone until the evaporation of acetone represented one session. Each stock solution was ground for three sessions of 20 minutes, then the powders were combined, and the solution was ground for one session of 20 minutes. The resulting mixture was baked in a high temperature oven to fully dehydrate/devolatilize the mixture.

1.3.2 Laser Fusing

The powder mixtures (methods were described in section 1.3.1) had to be fused together into spheres, which could later be levitated within a vertical gas flow. Methods A and B of this section will expand upon the evolution of the laser fusing process, within the scope of the overall methodology. This process began with the addition sample powder into concave depressions on a copper hearth plate (Fig. 6). This plate was then positioned within the aerodynamic levitation laser furnace's laser hearth, with hearth rods fitted into slots on opposite sides of the hearth plate that facilitated the movement of the plate during the fusing process (Fig. 5). The individual allotments of powder were heated with the laser and the hearth plate was moved in small circles to encourage the formation of spheres as the powder fused together.

1.3.2.1 Method A

When fusing the powders into spheres, a range of initial powder masses were used with the expectation that the specific amounts would correlate with the diameter of the sphere produced. This was not always the case and initial powder masses greater than ~8 mg resulted in waste. Initial amounts of ~9-15 mg resulted in only a small portion of the powder fusing together, leaving behind a significant amount of residual powder in the depression of the hearth plate. Laser power during the powder fusion varied between 9% and 12% (corresponding temperatures could not be recorded within the hearth chamber), where values less than 9% did not cause the powder to fuse, but left a burnt discoloration. Using higher laser powers resulted in samples releasing tendrils of smoke, indicating loss of material, which would have altered the final composition of the samples.

The fused spheroids were seldom perfectly spherical, as was intended. They ranged between teardrop shapes, bean-like shapes, and other irregular, misshapen forms. The uneven and irregular fused samples were not stable in the gas flow, proving more likely to wobble and sometimes stick to the side of the nozzle during the levitation laser-heating process, potentially altering their final composition via loss of material due to contact with the nozzle. In an attempt to improve the sphericity of the fused samples, some were introduced into an air-driven mill, which was adapted from the original design of Bond (1951) (borrowed from John Hughes) (Nitkiewicz and Sterner, 1988). This involved placing the spheroid in a small, cylindrical chamber with interior walls that were covered in a coarse, abrasive

material (a strip of sandpaper). A small inlet to the chamber had a tube, which directed a jet of compressed air into the chamber. Gaps between the top and bottom panels and the cylinder portion of this tool allowed the incoming air to escape. This directed air flow caused the sphere to bounce along the rough cylinder walls, with the expectation that this pattern of movement would cause an evenly-dispersed abrasion and a more spherical resulting shape. The more extremely misshapen samples often became pressed against the top or bottom panels, rather than being agitated within the chamber as was intended. The abrader tool did improve the sphericity of samples which were imperfect, but already mostly spherical forms. This tool was deemed unnecessary for this process, as the mostly-spherical samples did not suffer the same difficulties during levitation as the more irregular forms.

1.3.2.2 Method B

This iteration of the laser fusing process is the same as what is outlined in the methods section 1.2.4.

This iteration of the laser fusing process began with 0.5-7.0 mg aliquots of sample powder, placed in evenly-dispersed concave depressions on a copper hearth plate (Fig. 6). This plate was then positioned within the aerodynamic levitation laser furnace's laser hearth (Fig. 5), where two guiding rods were attached to opposite sides of the hearth plate. These allowed the user the ability to move the plate in small circular motions during the fusing process, which encouraged the loose powder to fuse together into spheres. The powder in each depression on the plate was heated with the laser at power levels of 9% to 9.5% for ~10 second intervals,

where power levels of 10.5 or higher caused loss of sample material and power levels of 8.5 or lower did not have enough heat to fully fuse the powder together.

1.3.3 Polishing

The glass spheres vitrified during the levitation process (section 1.3.2) underwent a polishing before they could be analyzed with the XRD, SEM, or EPMA. The earlier methods of this process resulted in a single polished surface, which was acceptable for analysis with a low-vacuum SEM, but a dual polish was necessary for the other analysis techniques. The dual polish involved a coarse grinding step, on the opposite side from the polished surface, to create a base on which the sample rested (Fig. 18). The top surface was polished to a grit size of 0.25 μm , and being parallel to the base ground plane, ensured a level surface on which the sample could rest. This flat resting surface was necessary for the different analytical techniques. The polishing process underwent several alterations and improvements through the development of the glass synthesis methodology. The evolution of the polishing procedure stemmed from changes to the type of temporary epoxy which was used and the material (container or mold) within which the temporary epoxy was contained.

1.3.3.1 Method A

The initial temporary epoxy used for these glass samples was Crystalbond 509, which came as a soft, but solid, rod. Using the plastic handle of a screwdriver, fragments were removed by controlled blunt-force percussion. These pieces were

then placed in an aluminum dish, and then another aluminum dish was placed on top, trapping the flakes between the two layers. The same tool was then used to make small and soft taps on the base of the top dish, resulting in the powdering of the Crystalbond 509 without contamination or loss of material. A separate aluminum dish was set aside to provide a stage for the remainder of the polishing preparation. Care was taken to keep the base of the dish free from scratches or bends and a square of double-sided carbon tape adhered to the bottom of the inside of the dish. The crushed powder was poured into the inner diameter of the epoxy mold in use (which will be addressed further in this section), making sure to coat the carbon tape surface, thus avoiding the formation of bubbles or weakened structural integrity. The aluminum dish, along with the epoxy mold, Crystalbond 509, and sample, was placed on a hot plate and heated to 121° C until fully melted. It was then removed from the hot plate and left to sit for an hour. Once the Crystalbond 509 had cooled and hardened completely, the aluminum dish and carbon tape were peeled off, leaving a cylindrical puck of temporary epoxy, with the glass samples secured in place.

Epoxy molds with an inner diameter of 22.00 mm, an outer diameter of 25.30 mm, and a height of 18.90 mm, which will hence be referred to as Epoxy Mold 1, were adhered to double-sided carbon tape on an aluminum dish, with two glass samples evenly spaced within the inner diameter of the cylinder. The initial plan was to remove the puck, then to polish the top and bottom sides. The height of the cylinder made polishing both sides, without the removal of the puck, an unnecessary time drain. Cutting the cylinder to an appropriate height had the added risk of not

maintaining parallel planes, which was the primary purpose of the dual polish. Issues were encountered when removing the puck from the cylinder. Epoxy Mold 1 held tightly and stuck to the Crystalbond 509, resulting in the puck breaking in half or fracturing on the edges after pressure was applied to it. Epoxy Mold 1 was replaced by Epoxy Mold 2, with an inner diameter of 24.85 mm, an outer diameter of 29.15 mm, and a height of 30.95 mm. Assisted removal of the puck from both Epoxy Mold 1 and Epoxy Mold 2 was attempted using “PTFE Release Agent Dry Lubricant” (described as a “PTFE”-like spray), but this was counterproductive and resulted in the development of a film, which caught on and stuck to the cylinders and the puck and further hindered its removal. This cylinder allowed for the puck to be removed cleanly and without damage to the puck. However, when attempting to polish the glass sample using the uncontained puck, the heat from the friction of polishing caused the hardened temporary epoxy to warp out of shape, rendering it useless. Unable to polish parallel planes of glass sample, the top plane was polished and the sample remained secured within the puck during low-vacuum SEM analysis. This was a temporary fix to allow for sample analysis while the methodology continued to evolve, as the whole puck could not be used in high-vacuum SEM analysis or Mössbauer spectroscopy.

1.3.3.2 Method B

Brass molds with an outer diameter of 6.35 mm, an inner diameter of 4.35 mm, and a height of 6.45 mm were used to polish a single sample at a time. The brass was soft enough to be ground away during the process, and the reduction fragments did

not scratch the surface of the sample. However, this method did not allow for the polishing of parallel planes, requiring that the samples remain within the puck during SEM analysis.

After the sample received the final polish with 0.25 μm diamond suspension, the brass cylinder was placed in acetone and sonicated until the sample was released and all the Crystalbond 509 had dissolved. At this point, the sample was placed on double-sided carbon tape within the inner ring of Epoxy Mold 1 in an arrangement with other samples of the same composition. The puck was then created in the same fashion as previously mentioned in section 1.3.3.1. Once the carbon tape and aluminum dish were removed, the puck was lightly and slowly polished with the 0.25 μm diamond in suspension grit size to remove residual carbon tape, resulting in the parallel and level polished surfaces contained within the puck.

1.3.3.3 Method C

This iteration of the polishing process involved experimentation with different materials to contain the Crystalbond 509. Four different nylon flat washers (Washer A, B, C, and D) had respective outer diameter, inner diameter, and height measurements of: 19.050 mm, 12.827 mm, and 3.175 mm; 25.400 mm, 10.319 mm, and 1.588 mm; 11.113 mm, 5.080 mm, and 1.588 mm; 22.479 mm, 8.712 mm, and 1.575 mm. These were tested as potential replacements for the more ‘traditional’ epoxy molds. The washers’ reduced height/thickness measurements relative to the molds, could allow for more efficient and direct polishing of parallel planes in the intended dual polishing method.

Washer A was deemed to be too thick, requiring excessive time added to the polishing process. More than a millimeter of washer material had to be polished away before the top portion of the glass sample was even reached. Furthermore, despite the excessive thickness, the wider inner diameter caused a weakened structure in the Crystalbond 509 and diminished its capacity to contain the sample. Washer B was of an appropriate thickness. However, like washer A, its ratio of inner diameter to thickness resulted in increased fragility to the hardened Crystalbond 509. This caused the puck to fracture either when it was removed from the carbon tape or during the initial coarse polishing/grinding step, compromising its integrity and ability to hold the sample in place. Washer C also had a satisfactory thickness, and the inner diameter width relative to the thickness resulted in strong stability of the Crystalbond 509. The thickness of washer D was suitable, but with an inner diameter slightly wider than washer C, the hardened puck was noticeably less stable. These collective observations made washer C the temporary epoxy mold of choice, between these four nylon flat washers. Unfortunately, samples polished with these washers routinely developed scratches, varying from minor to deeper gouges in the glass surface. It was determined that the nylon material removed during polishing was hard enough to inflict damage on the sample surface. This meant that ultimately, the nylon flat washers were not an appropriate choice for the polishing process.

1.3.3.4 Method D

This method of the polishing process utilized the softer, polytetrafluoroethylene washers described in the methods section 1.2.6. Samples were adhered to double-sided carbon tape in an aluminum dish inside the inner ring of a polytetrafluoroethylene washer (0.25" thick, 0.141" outer diameter, 0.062" inner diameter) (Fig. 13). The inner ring was then filled with manually-powdered Crystalbond 509, using the process described in method A in section 1.3.3.1. This temporary epoxy was replaced in method E in section 1.3.3.5. On multiple occasions, when polishing samples that were set in Crystalbond 509 within the polytetrafluoroethylene washers, the friction of the polishing process softened the temporary epoxy enough that the samples rotated in place, which compromised attempts to achieve a dual polish.

1.3.3.5 Method E

This iteration of the polishing process is the same as what is outlined in the methods section 1.2.6.

This method utilized the same polytetrafluoroethylene washers described in section 1.3.3.4 (Fig. 13). The remaining vacant space around the sample was filled with Dentsply Caulk Orthodontist Powder, rather than the Crystalbond 509, which had been used in previous methods. One drop of Dentsply Caulk Orthodontist Resin was applied to the powder, and after an hour the resin hardened to form a temporary epoxy that encased the sample within the washer. Parallel sides of the washer and sample were ground down using silicon carbide CarbiMet abrasive pads

of decreasing grit sizes. Following grinding to expose flat, parallel surfaces on two sides, the upper surface was polished on microcloths sprayed with diamond suspensions.

High purity deionized water was applied to the silicon carbide pads during the grinding steps. Four abrasive pads with increasingly fine grit sizes of 240, 320, 600, and 800, and with respective approximate micron sizes of 52, 35, 15, and 13 were used. Between each of the abrasive pad grit sizes, the sample was sonicated in water to remove residual grit and was then dried using a compressed tetrafluoroethane gas duster spray.

Polishing steps used MetaDi Supreme polycrystalline diamond suspension grit sizes of 6 μm , 3 μm , 1 μm , and 0.25 μm , which were applied to separate microcloths. Of the two exposed flat surfaces on the spheres, one side received only a coarse polish of the 240 grit-sized abrasive, while the other plane was polished with increasingly fine grit sizes culminating in 0.25 μm polycrystalline diamond suspension. As was the case with the silicon carbide pad steps, the washer/sample was sonicated in water between diamond suspension solution polishes to remove residual grit grains and debris. After the last polish, the sample was sonicated in isopropanol to avoid leaving acetone hydrocarbon residue, which could be picked up by the high-vacuum SEM.

1.3.4 Sample-Specific Methods Used

This section will detail the specific methods used for individual samples, as well as sample-specific measurements, like diameter and mass, and calculations, like

heating rate, cooling rate, and peak temperature during levitation. Tables 2 and 5 contain this information for each sample.

1.3.4.1 Non Fe-Bearing Compositions

1.3.4.1.1 Forsterite

To synthesize forsterite, a mixture containing a 2:1 molar ratio of MgO and SiO₂ powders (MgO was adjusted for 7.2% LOI) was created using the powder mixing method described in section 1.3.1.1. Both MgO and SiO₂ powders are white, making visual estimations of homogeneity impossible. Samples 7.11.17.15, 7.11.17.20, 8.4.17.1, 8.7.17.14, 8.7.17.20, and 8.7.17.21 with diameters ranging from 1.08 - 1.25 mm (Table 2), were levitated on mixtures of 20-25% Ar and 75-80% O₂ gases using a 90°/0.7 mm nozzle (Fig. 19 A). Heating rates for these samples were between 28°C/s and 317°C/s. Upon reaching peak temperatures between 173°C -2048°C, the laser power was cut off. Cooling rates varied according to the surface area of the individual glasses, spanning a range of 637°C/s to 941°C/s. These samples were all synthesized using powder preparation method A (section 1.3.1.1) and polishing method A (section 1.3.3.1). Sample 10.6.17.20 (diameter = 0.62 mm) was levitated and vitrified using a 60°/0.7mm nozzle (Fig. 19 C) with a mixture of 10% Ar and 90% O₂ gases. After heating at a rate of 28°C/s and reaching a peak temperature 1820°C, the sample cooled at a rate of 1606°C/s. Sample 10.6.17.20 was synthesized using powder preparation method B (section 1.3.1.2) and polishing method D (section 1.3.3.4). Sample 10.6.17.20 used a different nozzle (60°/0.7mm rather than 90°/0.7mm) (Fig. 19 C) than samples 7.11.17.15, 7.11.17.20, 8.4.17.1, 8.7.17.14,

8.7.17.20, and 8.7.17.21, which was a more appropriate nozzle aperture angle for the smaller diameter and improved sample stability on the gas flow.

1.3.4.1.2 Enstatite

The enstatite mixture came from a 1:1 molar ratio of the same stock MgO and SiO₂ powders as the forsterite batch, resulting in the composition MgSiO₃ (also taking the 7.2% MgO LOI into account). Using a 90°/1 mm nozzle (Fig. 19 B), samples with diameters varying between 1.37 mm and 1.60 mm were vitrified in 100% argon gas flows and heat rates between 148°C/s and 300°C/s. They were held at their peak temperature of between 2005°C and 2202°C for approximately 10 seconds before shutting off the laser power. The cooling rates varied by the surface area of the individual glasses, but overall they covered a range of 456°C/s to 611°C/s. For samples 7.11.17.2, 7.11.17.4, 7.31.17.3, 7.31.17.10, and 7.31.17.11, powder preparation method A (section 1.3.1.1) and polishing method B (section 1.3.3.2) were used. For sample 11.2.17.2, powder preparation method B (section 1.3.1.2) and polishing method D (section 1.3.3.4) were used.

1.3.4.1.3 Mg-Enriched Enstatite

To synthesize a glass with a composition similar to enstatite, but having excess MgO, a mixture containing a 2.5:1 molar ratio of MgO and SiO₂ powders (MgO mass was adjusted for 7.2% LOI) was created using the powder preparation method described in section 1.3.1.1. The intended composition for this mixture was Mg_{2.5}SiO₃. The Mg-enriched enstatite powder was fused using the laser fusing

method outlined in section 1.3.2.2, and polished using the method outlined in section 1.3.3.2. The levitation and vitrification of these samples varied slightly from that of the forsterite and enstatite samples.

Using a 90°/0.7 mm nozzle (Fig. 19 A), two samples with diameters of 1.04 mm and 1.14 mm were vitrified with 10% Ar and 90% O₂ gas flows and heat rates of 74 °C/s and 20 °C/s, respectively. As was the case with the forsterite samples, the slower heat rates were a result of carefully maintaining sample balance on the gas flow. When the peak temperatures of 1926 °C and 1953 °C, respectively, were reached for each sample, the laser power was stopped. The cooling rates were 896 °C/s and 826 °C/s, respectively.

1.3.4.2 Fe-Bearing Compositions

1.3.4.2.1 En95

Version 2 of the En95 mixture was prepared using powder preparation method B (section 1.3.1.2), laser fusing method B (section 1.3.2.2), and polishing method D (section 1.3.3.4). Like version 1, the intended formula was (Mg_{0.95}Fe_{0.05})SiO₃. This En95 mixture took the MgO 7.2% LOI into account as well as a 10% LOI of the Fe₂O₃. The LOI of the Fe₂O₃ was accounted for in all later versions as well. Eight of the samples synthesized from version 2 mixtures (11.30.17.2, 11.30.17.4, 3.28.18.1, 3.28.18.5, 3.28.18.6, 3.28.18.8, 3.28.18.11, and 3.28.18.12) were analyzed by SEM. Using a 90°/1 mm nozzle (Fig. 19 B), two samples (11.30.17.2 and 11.30.17.4) with diameters of 1.19 mm and 1.24 mm, respectively, were vitrified within 100% O₂ gas flows and 11.30.17.2 was heated at a rate of 13 °C/s. When the peak temperatures of

2000 °C and 2100 °C, respectively, were reached for each sample, the laser power was stopped. The cooling rates were 687 °C/s and 335 °C/s, respectively.

An additional six samples were created using a 90°/0.7 mm nozzle (Fig. 19 A), (3.28.18.1, 3.28.18.5, 3.28.18.6, 3.28.18.8, 3.28.18.11, and 3.28.18.12) with respective diameters of 1.63 mm, 1.37 mm, 0.99 mm, 1.29 mm, 1.21 mm, and 1.01 mm. These samples were vitrified within varied gas compositions, which will be expanded upon in section 1.4.2.3, and heat rates ranging between 88 °C/s and 119 °C/s. When the peak temperatures reached between 1840 °C and 1993 °C, the laser power was stopped and the samples cooled at rates ranging between 385 °C/s and 764 °C/s. Two of the eight En95 samples analyzed with the SEM (3.28.18.8 and 3.28.18.12) stuck to the side of the conical nozzle at some point during the levitation process. These samples showed the least accurate and precise weight percentages.

Version 4 of the En95 mixture used powder preparation method C (section 1.3.1.3), laser fusing method B (section 1.3.2.2), and polishing method E (section 1.3.3.5). The intended formula was $(\text{Mg}_{0.95}\text{Fe}_{0.05})(\text{Si}_{0.95}\text{Fe}_{0.05})\text{O}_3$, and all six of the analyzed samples (6.22.18.1, 6.22.18.2, 6.22.18.3, 6.22.18.4, 6.22.18.5, and 6.22.18.6) were levitated in a gas mixture with a composition of 80% of 5% CO₂ in Ar and 20% of 5% CO in Ar, using a 90°/1 mm nozzle (Fig. 19 B). They had respective diameters of 1.51 mm, 1.51 mm, 1.50 mm, 1.47 mm, 1.39 mm, and 1.33 mm. These samples had heat rates ranging between 182 °C/s and 234 °C/s, peak temperatures reaching between 1949 °C and 2031 °C, and cooling rates ranging between 393 °C/s and 509 °C/s.

1.3.4.2.2 En90

Version 1 of the En90 mixture was prepared using powder preparation method B (section 1.3.1.2), laser fusing method B (section 1.3.2.2), and polishing method E (section 1.3.3.5). The intended formula was $(\text{Mg}_{0.9}\text{Fe}_{0.1})\text{SiO}_3$, which was the target chemical composition for all three versions of this mixture. All three versions took both a 7.2% MgO LOI into account as well as the 10% Fe_2O_3 LOI. Two samples from a version 1 mixture were analyzed by SEM. Using a 90°/1 mm nozzle (Fig. 19 B), samples 1.5.18.4 and 1.5.18.10 had respective diameters of 1.81 mm and 1.23 mm and were synthesized within 100% O_2 gas flows. The samples had respective heat rates of 23°C/s and 24°C/s, peak temperatures of 2243°C and 2250°C, and cooling rates of 446°C/s and 751°C/s (Table 2).

Version 3 of the En90 mixture was created using powder preparation method C (section 1.3.1.3), laser fusing method B (section 1.3.2.2), and polishing method E (section 1.3.3.5). The intended formula was $(\text{Mg}_{0.9}\text{Fe}_{0.1})\text{SiO}_3$, and all three of the analyzed samples (6.21.18.2, 6.21.18.3, and 6.21.18.5) were levitated within a gas flow with a composition of 100% O_2 , using a 90°/1 mm nozzle (Fig. 19 B). These samples had diameters of 1.26 mm, 1.29 mm, and 1.18 mm, respectively, with heat rates ranging between 214 °C/s and 536 °C/s, peak temperatures reaching between 1948 °C and 2089 °C, and cooling rates ranging between 615 °C/s and 705 °C/s.

1.4 Results

This section will detail the results from the XRD, SEM, and EPMA analyses for each intended composition. The section is sub-divided first by the lack/presence of

iron and then by the specific composition of the samples. The non Fe-bearing samples include the forsterite, enstatite, and Mg-enriched enstatite compositions, and the Fe-bearing samples include the different versions of the En95 and En90 compositions, followed by an inspection of the visual effects of fugacity constraints on the En95 composition samples.

1.4.1 Non Fe-Bearing Compositions

1.4.1.1 Forsterite

All samples were analyzed using the TESCAN VEGA3 SEM at the University of Illinois in Urbana-Champaign as described in section 1.2.8. For samples 7.11.17.15, 7.11.17.20, 8.4.17.1, 8.7.17.14, and 10.6.17.20, multiple spots were analyzed with the EDS detector to acquire x-ray spectra and determine compositions (Fig. 17; Tables 3 and 4). The analyses were done moving from the center of the exposed surface of the sphere toward an edge to gain a better assessment of sample homogeneity from core to rim. Two of the samples (8.7.17.20 and 8.7.17.21) had large internal bubbles which were cut by the polished surface and only had room for one spot to analyze on each (Fig. 20).

(Fig. 21; Table 4) shows that from 7.11.17.15, 7.11.17.20, 8.4.17.1, 8.7.17.14, and 10.6.17.20, samples 7.11.17.15 and 10.6.17.20 had the most accurate oxide percentages, with 57.27 ± 1.05 wt% MgO and 57.69 ± 0.73 wt% MgO, respectively, and 42.73 ± 1.05 wt% SiO₂ and 42.31 ± 0.73 wt% SiO₂, respectively. Samples 8.7.17.20 and 8.7.17.21 each have one assessed spot due to limited accessible areas, with 58.76 wt% MgO and 57.12 wt% MgO, respectively, and 41.24 wt% SiO₂ and

42.88 wt% SiO₂, respectively. Samples 7.11.17.20 and 8.7.17.14 both show percentages less than the target value within 3.5%, with 54.68 ± 0.71 wt% MgO and 55.14 ± 1.96 wt% MgO, respectively, and 45.32 ± 0.71 wt% SiO₂ and 44.86 ± 1.96 wt% SiO₂, respectively. The forsterite sample with both the least accurate and the least precise MgO and SiO₂ percentages is 8.4.17.1. These spots are an average of 10.9% less than the target value, with 46.42 wt% MgO and 53.58 wt% SiO₂. Sample 7.11.17.15 was the most accurate.

Samples 10.6.17.6 and 10.6.17.8 had irregular external textures (Fig. 14), indicating that they may have crystallized (devitrified) upon quenching. These samples were analyzed on the XRD to check for devitrification. Using the Vantec detector, the interatomic spacing in the samples was assessed, seeking to discover whether there was a repeated, crystalline characteristic to the material or whether the internal structure was amorphous. The results showed a single Bragg's peak rising from a broad and shallow background (Fig. 15). The peak indicates partial devitrification, while the shallow background indicates the remainder of the sample having an amorphous structure. The peak was located at a 2-theta distance of 17.97, which correlates with an interatomic spacing for forsterite (according to the reference distances in the Bruker D8 Discover software).

Sample 10.6.17.20 was analyzed, using both the LynxEye and Vantec detectors, where the LynxEye scan was a more thorough and time-consuming analysis that fired x-rays at the sample in angle increments of 0.01° as opposed to the 1.5° of the Vantec scan. After the Vantec scan did not identify any crystallinity in the sample, the LynxEye detector was used to confirm the accuracy of the Vantec scan and the

amorphous internal structure of the sample (Fig. 16). Both scans showed broad and shallow curves with maximums centered near the forsterite 2-theta distances, but were absent of Bragg's peaks which would have been indicative of crystal growth within the sample, indicating that this sample was completely vitrified.

1.4.1.2 Enstatite

Five polished enstatite glasses mounted in Crystalbond 509 and one enstatite glass adhered to a glass slide were analyzed using the TESCAN VEGA3 SEM at the University of Illinois in Urbana-Champaign. Perfectly stoichiometric enstatite (MgSiO_3) should contain 40.15 wt% MgO and 59.85 wt% SiO_2 , making it the target composition of these samples.

The enstatite samples generally showed greater accuracy and precision than the forsterite compositions (Tables 3 and 4). Samples 7.11.17.4, 7.31.17.10, and 7.31.17.11 were all close to the goal composition, with 41.54 ± 0.91 wt% MgO, 39.56 ± 0.68 wt% MgO, and 39.54 ± 0.54 wt% MgO, respectively, and 58.46 ± 0.91 wt% SiO_2 , 60.44 ± 0.68 wt% SiO_2 , and 60.46 ± 0.54 wt% SiO_2 , respectively. Samples 7.31.17.3 and 11.2.17.2 were the most precise. The accuracy of 7.31.17.3 fell short of the intended composition with 35.10 ± 0.05 wt% MgO and 64.90 ± 0.05 wt% SiO_2 , while sample 11.2.17.2 had 41.26 ± 0.05 wt% MgO and 58.74 ± 0.05 wt% SiO_2 . The remaining enstatite sample 7.11.17.2 also showed 35.38 ± 0.61 wt% MgO and 64.62 ± 0.61 wt% SiO_2 . Sample 7.31.17.10 was the most accurate sample and 7.31.17.11 was the most precise sample (Tables 3 and 4; Fig. 22).

1.4.1.3 Mg-enriched Enstatite

Like the forsterite and enstatite samples, the polished Mg-enriched glasses were analyzed using the TESCAN VEGA3 SEM at the University of Illinois in Urbana-Champaign. The samples were synthesized using powder preparation method A (section 1.3.1.1), laser fusing method B (section 1.3.2.2), and polishing method B (section 1.3.3.2) (Table 5). According to the stoichiometry of this Mg-enriched enstatite ($\text{Mg}_{2.5}\text{SiO}_3$), the glasses synthesized from this mixture should contain 62.65 wt% MgO and 37.35 wt% SiO_2 . Mg-enriched enstatite samples 8.14.17.7 and 8.14.17.8 had 53.53 ± 0.37 wt% MgO and 50.62 ± 2.9 wt% MgO and 46.47 ± 0.37 wt% SiO_2 and 49.38 ± 2.9 wt% SiO_2 , respectively. Sample 8.14.17.7 was the more accurate of the two samples (Tables 3 and 4).

1.4.2 Fe-Bearing Compositions

The Fe-bearing compositions described in this section include En95 and En90, with an additional section examining the effects of f_{O_2} constraints on En95 compositions. The En95 samples are enstatite compositions, where the Mg cation site consists of 95% Mg versus 5% Fe. Similarly, the En90 samples are enstatite compositions, where the Mg cation site consists of 90% Mg versus 10% Fe.

1.4.2.1 En95

During the progression of this research, there were four different versions of the 95% Mg – 5% Fe enstatite (here these are referred to as En95), each of which reflected different stages of the evolution of the methodology and/or varied

intended chemical compositions. These are described below. Of the four versions, only versions 2 and 4 were analyzed with the SEM and EPMA, respectively.

1.4.2.1.1 Version 1

The first En95 mixture was prepared using powder preparation method A (section 1.3.1.1), laser fusing method B (section 1.3.2.2), and polishing method D (section 1.3.3.4) (Table 5). The intended formula was $(\text{Mg}_{0.95}\text{Fe}_{0.05})\text{SiO}_3$, and the mixtures were created from MgO , SiO_2 , and Fe_2O_3 powders, accounting for a 7.2% LOI of the MgO . This version was created prior to the first semi-quantitative SEM analysis, which had showed the powder preparation process to be lacking.

1.4.2.1.2 Version 2

The intended oxide weight percentages for En95-version 2 are 37.55 wt% MgO , 58.93 wt% SiO_2 , and 3.52 wt% Fe_2O_3 . The samples levitated in 100% O_2 (11.30.17.2, 11.30.17.4, and 3.28.18.5) had 45.73 ± 1.3 wt% MgO , 43.34 ± 1.4 wt% MgO , and 40.78 ± 0.6 wt% MgO , 53.63 ± 1.0 wt% SiO_2 , 54.83 ± 0.4 wt% SiO_2 , and 55.07 ± 0.1 wt% SiO_2 , and 0.63 ± 0.3 wt% Fe_2O_3 , 1.82 ± 1.6 wt% Fe_2O_3 , and 4.15 ± 0.6 wt% Fe_2O_3 . The sample vitrified under 100% Ar (3.28.18.1) had 39.60 ± 1.2 wt% MgO , 57.16 ± 0.1 wt% SiO_2 , and 3.24 ± 1.2 wt% Fe_2O_3 . The sample levitated in a gas mixture of 5% CO_2 in Ar (3.28.18.6) had 40.19 ± 1.0 wt% MgO , 57.05 ± 0.1 wt% SiO_2 , and 2.76 ± 1.0 wt% Fe_2O_3 . The sample levitated in a gas mixture of 50% Ar and 50% O_2 (3.28.18.8) had 45.24 ± 5.2 wt% MgO , 52.81 ± 4.2 wt% SiO_2 , and 1.95 ± 1.8 wt% Fe_2O_3 . The sample levitated in a gas mixture of 5% CO in Ar (3.28.18.11) had $41.67 \pm$

2.3 wt% MgO, 56.56 ± 0.4 wt% SiO₂, and 1.77 ± 2.4 wt% Fe₂O₃. The last sample, levitated in a gas mixture of 50% of 5% CO₂ in Ar and 50% of 5% CO in Ar (3.28.18.12) had an MgO percentage of $59.98 \pm 6.2\%$, an SiO₂ percentage of $39.99 \pm 6.2\%$, and an Fe₂O₃ percentage of $0.03 \pm 0.0\%$. The most accurate sample was 3.28.18.1 (Fig. 23).

1.4.2.1.3 Version 3

This En95 mixture was prepared using powder preparation method C (section 1.3.1.3), laser fusing method B (section 1.3.2.2), and polishing method E (section 1.3.3.5). The intended formula was (Mg_{0.95}Fe_{0.05})SiO₃. The products of this version were being polished when the intended formula was altered in what is version 4.

1.4.2.1.4 Version 4

This mixture was analyzed with the EPMA which evaluated the elemental composition of each sample at between 35 and 48 individual spots (Tables 6 and 7). The six samples, listed in ascending order (6.22.18.1, 6.22.18.2, 6.22.18.3, 6.22.18.4, 6.22.18.5, and 6.22.18.6), had 36.92 ± 0.2 wt% MgO, 37.06 ± 0.1 wt% MgO, 37.37 ± 0.1 wt% MgO, 36.88 ± 0.2 wt% MgO, 37.11 ± 0.1 wt% MgO, and 36.69 ± 0.1 wt% MgO, with a target 37.05 wt% MgO. They had, respectively, 54.73 ± 0.4 wt% SiO₂, 54.83 ± 0.3 wt% SiO₂, 55.26 ± 0.3 wt% SiO₂, 54.75 ± 0.4 wt% SiO₂, 54.86 ± 0.3 wt% SiO₂, and 54.37 ± 0.3 wt% SiO₂, with a target 55.23 wt% SiO₂. They had, respectively, 8.34 ± 0.1 wt% Fe₂O₃, 8.37 ± 0.1 wt% Fe₂O₃, 8.38 ± 0.1 wt% Fe₂O₃, 8.37 ± 0.1 wt%

Fe₂O₃, 8.37 ± 0.0 wt% Fe₂O₃, and 8.38 ± 0.0 wt% Fe₂O₃, with a target 7.73 wt% Fe₂O₃. The most accurate sample was 6.22.18.6 (Fig. 24).

1.4.2.2 En90

During the progression of this research, there were three different versions of the 90% Mg – 10% Fe enstatite (En90), each of which reflected different stages of the evolution of the methodology. Of these versions, only versions 1 and 3 were analyzed with the SEM and EPMA, respectively.

1.4.2.2.1 Version 1

The intended oxide weight percentages for En90 are 34.76 wt% MgO, 57.58 wt% SiO₂, and 7.65 wt% Fe₂O₃. Samples 1.5.18.4 and 1.5.18.10 had 40.02 ± 1.8 wt% MgO and 37.70 ± 2.5 wt% MgO, 59.98 ± 1.8 wt% SiO₂ and 62.30 ± 2.5 wt% SiO₂, and 1.71 ± 1.5 wt% Fe₂O₃ and 4.12 ± 2.6 wt% Fe₂O₃. The most accurate sample was 1.5.18.10 (Fig. 25).

1.4.2.2.2 Version 2

This En90 mixture was prepared using powder preparation method C (section 1.3.1.3), laser fusing method B (section 1.3.2.2), and polishing method E (section 1.3.3.5). The intended formula was (Mg_{0.9}Fe_{0.1})SiO₃. Before these samples could be analyzed, the calculations determining the initial mass ratios of the oxide powders for the powder preparation method was changed. The products of this version were being polished when the initial stock solution masses were reevaluated (Table 5).

1.4.2.2.3 Version 3

Version 3 was assessed with the EPMA, resulting in elemental analyses of each sample at between 41 and 72 individual spots (Tables 6 and 7). The three samples, (6.21.18.2, 6.21.18.3, and 6.21.18.5), had 57.10 ± 0.4 wt% SiO₂, 56.79 ± 0.7 wt% SiO₂, and 56.96 ± 0.4 wt% SiO₂, respectively, with a target 57.58 wt% SiO₂. The samples had 34.90 ± 0.1 wt% MgO, 34.82 ± 0.5 wt% MgO, and 35.38 ± 0.1 wt% MgO, respectively, with a target 34.76 wt% MgO. The samples had 8.18 ± 0.1 wt% Fe₂O₃, 8.19 ± 0.1 wt% Fe₂O₃, and 8.22 ± 0.1 wt% Fe₂O₃, respectively, with a target 7.65 wt% Fe₂O₃. The most accurate sample was 6.21.18.3 (Fig. 26).

1.4.2.3 Visual Effects of Fugacity Constraints

Twelve En95 samples with an intended composition of Mg_{0.95}Fe_{0.05}SiO₃, created using the methods outlined in section 1.2, were synthesized in various gas environments, as described in previous sections, to determine correlations between f_{O_2} of the levitation gas mixture and visual characteristics of the glasses (Figs. 27 A-M (levitated glasses)). For six different gas mixture scenarios that were heated to 1800 °C, one sample was held at peak temperature for 30 seconds and one sample was held at peak temperature for 60 seconds. As a result, for each of the six gas mixtures used, two glass samples were created. Four of these f_{O_2} conditions involved levitation using a pure gas, or a premixed batch of two gases contained in a single gas cylinder: pure Ar, pure O₂, a premixed cylinder of 5% CO in Ar, and a premixed cylinder of 5% CO₂ in Ar.

The remaining two f_{O_2} conditions involved combining/mixing (in the levitation furnace) gases from either the gas cylinders containing a pure gas or from the cylinders with the premixed gases; the combinations investigated here were: (1) 50% Ar plus 50% O_2 and (2) 50% of the 5% CO in Ar plus 50% of the 5% CO_2 in Ar. Levitation experiments were run using the same proportional-integral-derivative (PID) conditions, except for holding time, which was either one of two durations: 30 seconds or 60 seconds. The PID settings were chosen to achieve a consistent heating rate of 100 °C/s. The measured heating rates varied between 85 °C/s and 120 °C/s, with the exception of sample 3.28.18.13 which had a heat rate of 285 °C/s. The gas flow rates on which the samples levitated were varied between different samples, as the flow rates were dependent on the sample size, mass, and shape variations. The diameter of each sample can be found in Table 2. Each of the 30 second hold-time samples was polished and analyzed with the SEM.

The samples synthesized in pure O_2 (3.28.18.4 and 3.28.18.5) had a brown color after levitation and vitrification (Figs. 27 D and 27 E), while the samples synthesized in 50% Ar and 50% O_2 (3.28.18.8 and 3.28.18.9) had a brownish-green coloration (Figs. 27 H and 27 I). Sample 3.28.18.3 was also synthesized in O_2 , however this sample stuck to the side of the nozzle during levitation and nucleated on contact (Fig. 27 C). The remaining glasses all had varying shades of green. The 100% Ar samples (3.28.18.1 and 3.28.18.2) (Figs. 28 A and 28 B), the samples that were entirely 5% CO_2 in Ar (3.28.18.6 and 3.28.18.7) (Figs. 27 F and 27 G), and the 50/50 mix of 5% CO_2 in Ar plus 5% CO in Ar sample held at temperature for 60 seconds (3.28.18.13) presented with pale green colors (Fig. 27 M). The samples that were

entirely 5% CO in Ar (3.28.18.10 and 3.28.18.11) had a blue-green color (Figs. 27 J and 27 K), as did the 50% of the 5% CO₂ in Ar and the 50% of the 5% CO in Ar sample held at temperature for 30 seconds (3.28.18.12) (Fig. 27 L).

The SEM results from the six samples held at peak temperature for 30-second intervals (3.28.18.1, 3.28.18.5, 3.28.18.6, 3.28.18.8, 3.28.18.11, and 3.28.18.12) were detailed in the En95 section 1.4.2.1 (Tables 3 and 4).

1.5 Discussion

1.5.1 Non Fe-Bearing Compositions

1.5.1.1 Forsterite

The forsterite glasses were the most difficult to synthesize, due primarily to the fragility of the melt for this composition. As mentioned in section 1.1.1, forsterite requires fast cooling rates in order to vitrify and avoid recalescence (Debenedetti & Stillinger, 2001; Miura et al., 2010; Moynihan, 1995; Nagashima et al., 2008; Tangeman et al., 2001; Webb, 1997; Weber & Benmore, 2017). The samples are cooled by cutting off the laser power, rather than via controlled cooling by gradually lowering the laser power over time, which leads to the fastest possible quenching for a given sample diameter. However, by fusing smaller samples, we were able to reduce the amount of surface area by reducing the sample diameter. This led to slightly faster cooling rates for smaller spheres. Diameters less than or close to 1 mm can achieve high enough cooling rates to exceed the structural relaxation rate and avoid crystallization. Previous research determined that the minimum cooling rate for forsterite vitrification in pure O₂ was 700 °C/s, as samples with cooling

rates between 250 °C/s and 700 °C/s resulted in crystallization (Tangeman et al., 2001). The glasses synthesized in this research, which were levitated in varying combinations of Ar and O₂ gases, recorded cooling rates of between 637 °C/s and 1606 °C/s for sample diameters ranging between 0.62 mm and 1.25 mm (Fig. 28).

Smaller samples were difficult to levitate with stability within the gas flows. These balance issues were directly tied to the heating rate for smaller samples. Slower heating rates were utilized to keep the molten spheres centered in the gas flow. Heating too quickly caused the samples to wobble within the flow and then stick to the side of the nozzle, causing them to significantly lose their form and often nucleate on contact. By incrementally increasing the laser power and decreasing the gas flow, the smaller samples were able to maintain stability. This progression resulted in lower heating rates with longer heating durations. Larger samples were less affected by the passing gas flows and were able to be heated more rapidly.

The six forsterite samples analyzed by SEM using powder preparation method A (section 1.3.1.1) showed a lack of consistent accuracy and homogeneity, though half of them did achieve oxide percentages close to the intended target. Two of those samples were only analyzed with a single spot analysis, due to the presence of vesicles intersecting the polished surface. The forsterite sample that used powder preparation method B (section 1.3.1.2) (10.6.17.20) showed a tight grouping of accurate spot analyses (Fig. 21).

The internal structure for three of the forsterite samples (10.6.17.6, 10.6.17.8, and 10.6.17.20) was assessed by XRD, successfully confirming that an amorphous internal structure of a glass could be visually determined by smooth external

textures and transparency. Two samples (10.6.17.6 and 10.6.17.8) had exterior textures like crumpled paper (Fig. 14) (discussed in sections 1.2.7 and 1.4.1.1), though the material was transparent and the temperature vs time data from the levitation run showed no evidence of recalescence. The results from the XRD's Vantec detector showed a single crystalline peak for each sample, above an otherwise broad and shallow background. Bragg's peaks are clear indicators of crystalline structure, whereas the low-intensity curves that extend across a wide variety of interatomic spacing distances are evidence of an amorphous structure. The combination of these two features indicated that the samples had each nucleated on the inside and, rather than crystallizing completely, had collapsed inward resulting in the crumpled exterior texture. This resulted in primarily amorphous internal structures, with microcrystalline inclusions. This could have been caused by dust particles in the levitation chamber that interacted with the cooling sample and provided contact points from which nucleation began to occur. As no other samples that were transparent presented with varied exterior textures, this theory was not tested and is only speculation. Sample 10.6.17.20, which was transparent with a smooth surface, was analyzed with both the Vantec detector and the LynxEye detector of the XRD, and showed a complete lack of crystalline peaks, confirming an amorphous structure.

1.5.1.2 Enstatite

As opposed to forsterite, the enstatite composition yields a very strong melt. So, barring contact with the nozzle or some other contact nucleation site, the samples

easily vitrified upon cooling within a wide range of cooling rates. As extreme cooling rates were not required, the enstatite samples were able to have greater diameters than the forsterite samples, which granted them better stability within the gas flows. The six enstatite samples analyzed with the SEM (7.11.17.2, 7.11.17.4, 7.31.17.3, 7.31.17.10, 7.31.17.11, and 11.2.17.2) were all levitated in pure Ar, using powder preparation method A (section 1.3.1.1) and laser fusing method B (section 1.3.2.2). Polishing method B (section 1.3.3.2) was used for samples 7.11.17.2, 7.11.17.4, 7.31.17.3, 7.31.17.10, and 7.31.17.11. Powder preparation method B (section 1.3.1.2), laser fusing method B (section 1.3.2.2), and polishing method D (section 1.3.3.4) were used for sample 11.2.17.2.

Samples 7.31.17.10, 7.31.17.11, and 11.2.17.2 were all within 1.11% of the target weight percentages with minimal variation between individual spots of less than 0.68% (Tables 3 and 4; Fig. 22). However, the remaining two samples were created from the same batch and though they showed tight grouping of the individual spot analyses, accuracy was poor. For sample 7.11.17.2, multiple vitrification attempts were made on the same sample. Contact nucleation with the nozzle on earlier attempts could account for the compositional inconsistencies. This does not explain the inaccuracy of sample 7.31.17.3, which vitrified on its first run and had oxide weight percentages more than 5.5% from the intended value. Sample 11.2.17.2, which employed the more rigorous powder preparation process, was very accurate and precise.

1.5.1.3 Mg-enriched Enstatite

Enriched enstatite samples were synthesized with the intention of achieving the composition $\text{Mg}_{2.5}\text{SiO}_3$. They were prepared using the same methods as the bulk of forsterite and enstatite samples, using powder preparation method A (section 1.3.1.1), laser fusing method B (section 1.3.2.2), and polishing method B (section 1.3.3.2). The two samples (8.14.17.7 and 8.14.17.8) were levitated with a gas mixture of 90% O_2 and 10% Ar, with relatively low heating rates due to stability within the gas flow and high cooling rates, which were possible because they had relatively small diameters of 1.04 mm and 1.14 mm, respectively. The SEM spot analyses of the samples showed them both to be significantly depleted in MgO, by 9.1% and 12.0%, respectively. The MgO values were even less than the 57.29% intended for the forsterite composition, revealing them to not be Mg-enriched glasses. As powder preparation method A (section 1.3.1.1) was employed for these samples, the initial mixing was less rigorous and could have been the cause of compositional heterogeneities within the individual samples.

1.5.2 Fe-Bearing Compositions

1.5.2.1 En95

Four different En95 versions were created: (1) Version 1; (2) Version 2; (3) Version 3; (4) Version 4. Version (1) glasses did not undergo SEM analysis before the next version of the methodology was in effect. Version (2) glasses, samples 11.30.17.2, 11.30.17.4, 3.28.18.1, 3.28.18.5, 3.28.18.6, 3.28.18.8, 3.28.18.11, and 3.28.18.12, were synthesized using powder preparation method B (section 1.3.1.2),

laser fusing method B (section 1.3.2.2), and polishing method D (section 1.3.3.4), and had varied oxide weight percentages, the majority of which were depleted in Fe_2O_3 . Samples 3.28.18.1, 3.28.18.5, 3.28.18.6, 3.28.18.8, 3.28.18.11, and 3.28.18.12 were each levitated within different gas mixes, with the goal of determining correlations between the color of the glasses produced and their environments during vitrification. The three samples vitrified under 100% O_2 (11.30.17.2, 11.30.17.4, and 3.28.18.5) showed a range of weight percentages, with MgO and SiO_2 values more than 3% from the intended composition, and inconsistent Fe_2O_3 percentages. Samples 3.28.18.1, 3.28.18.6, 3.28.18.8, 3.28.18.11, and 3.28.18.12 were each synthesized under different gas environments, with the most accurate results coming from the sample vitrified in 100% Ar, though the spot analyses showed heterogeneities within the sample. The least accurate and precise results came from the two samples which came in contact with the side of the conical nozzle during levitation. Contact with the metal clearly resulted in leaching of material, significantly reducing the weight percentage of Fe_2O_3 and causing the ratio of MgO and SiO_2 to vary dramatically across each of the samples.

Version (3) glasses were being polished for SEM analysis when the methodology was changed and the intended formula changed from $(\text{Mg}_{0.95}\text{Fe}_{0.05})\text{SiO}_3$ to $(\text{Mg}_{0.95}\text{Fe}_{0.05})(\text{Si}_{0.95}\text{Fe}_{0.05})\text{O}_3$. Version (4) glasses showed consistently accurate weight percentages, with clear homogeneity across the six samples (6.22.18.1, 6.22.18.2, 6.22.18.3, 6.22.18.4, 6.22.18.5, and 6.22.18.6). These glasses were made using powder preparation method C (section 1.3.1.3), laser fusing method B (section 1.3.2.2), and polishing method E (section 1.3.3.5). These quantitative EPMA results

are from approximately 10 times as many spot analyses as the semi-quantitative SEM results, and show accuracy and precision across each sample. All the samples are within 1% of the intended weight percentage with a variability of 0.4% or less within each sample. The Fe_2O_3 results were consistent across the samples and within each sample, all of which were slightly enriched around 8.37% relative to the intended 7.73%. This could be due to an overestimation of the LOI for the Fe_2O_3 powder, where more of the stock solution than necessary was added in the powder preparation step described in section 1.2.4. If less material than expected was actually lost, the unanticipated residual could account for the excess in the EPMA results.

1.5.2.2 En90

Three different En90 versions were created: (1) Version 1; (2) Version 2; (3) Version 3. The oxide weight percentages of two glasses (1.5.18.4 and 1.5.18.10) from version (1) were determined by SEM multiple spot analyses. Both samples showed excessive MgO and SiO_2 weight percentages, with depleted Fe_2O_3 percentages. In addition to sufficiently lacking in accuracy, both had margins of error between 1.5% and 2.5%, showing an inconsistent composition both within the prepared batch of powder as well as within the individual samples.

Version (3) glasses (6.21.18.2, 6.21.18.3, and 6.21.18.5) were assessed by EPMA from between 41 and 72 individual spot analyses. These results showed the glasses to be very accurate and precise, with oxide weight percentages all falling within 1% of the target amounts and with a maximum margin of error of 0.7%. All of the Fe_2O_3

weight percentages were higher than intended, by approximately 0.5%. As was the case for the En95 glasses, this is likely due to an overestimation of the LOI for the initial Fe_2O_3 stock solution powder.

1.6 Summary and Conclusions

Throughout the course of this research, and after myriad iterations of the various steps involved in synthesizing homogeneous glasses with accurate compositions, a rigorous methodology evolved, to consistently create compositionally accurate and precise materials. Early versions of the different intended chemical compositions showed inaccuracies and imprecisions, which fundamentally altered and drove the methodology changes. Increasing the thoroughness with which the initial stock solutions were mixed and making adjustments to the intended chemical composition have resulted in consistently accurate and homogeneous Mg-Fe enstatite glasses. The quantitative results of this research show that the intended compositions were achieved with minimal error, and defend the claim that the final methodology presented in section 1.2 consistently produces compositionally accurate and homogeneous glasses. The final version of this methodology will be used to vitrify ^{57}Fe -bearing Mg-Fe enstatites in oxidizing and reducing environments, with the goal of producing samples with a range of ferric $(\text{Mg}_{0.95}\text{Fe}_{0.05})^{III}(\text{Fe}_{0.05}\text{Si}_{0.05})\text{O}_3$ and ferrous $(\text{Mg}_{0.9}\text{Fe}_{0.1}\text{SiO}_3)$ iron.

The success of this methodology has direct implications for deep Earth petrology and geophysics. The ability to produce accurate and homogeneous glasses with the chemical compositions of the mantle's primary minerals ensures consistent starting

materials for simulations of the lower mantle environment. Where natural mineral samples exhibit compositional variations, glasses preserve accuracy and homogeneity to a micron scale. Having these starting materials allows experiments simulating the pressure and temperature conditions near the core-mantle boundary to be replicated, without the need to account for compositional heterogeneities within each sample or between samples of the same intended composition.

Chapter 2: R Shiny Applications

2.1 LaserPlot

2.1.1 Introduction

When interpreting and analyzing the data output files from levitation experiments using the aerodynamic levitation laser furnace, there were many difficulties and steps required. The relevant data for plotting didn't appear until after 121 lines of the spreadsheet. At this point the data recording began, but the experiment began a variable amount of time later. Initial efforts to filter these data and retrieve necessary conditions of the experiment required sizeable manual user input for each file. This involved the creation of an Excel file, which was able to produce quality plots and synthesize information, but required significant time and energy. As a solution to these complications, LaserPlot was created.

LaserPlot is a browser application built specifically for the Microsoft Excel 97-2003 formatted data output from the aerodynamic levitation laser furnace. The coding is in the language of R and it employs the Shiny package, which runs the code in the background and displays a clean graphical user interface in the browser page. The full source code can be viewed via the hyperlink in Appendix A. The application has the capability to produce high-quality plots of temperature vs time and laser power vs time, in addition to automatically running derivation calculations, linear regressions, and pulling important information from the loaded Excel file. All this information is then sorted and available to download as a CSV file, and the plots are available as either PDF or PNG files.

2.1.2 Motivation

The structure of the output file from the aerodynamic levitation laser furnace includes a lot of detail, which makes it time consuming to extract and assess the relevant information. In order to reduce the processing time, LaserPlot was developed. The first 121 rows of the file consists of machine information, including but not limited to: a list of Boolean vectors for specific machine settings, PID settings, the gases used during levitation and their relative percentages, the gas flow rate, and the date. After these lines, the data fall within eight variables, though only the time, corrected temperature, and laser power variables are of analytical importance. The file begins recording data from the time that it is manually initiated in the Materials Development Inc. laser software until the moment that it is manually stopped. This means that the relevant information within the file is contained within a range that begins where the corrected temperature readings are above the pyrometer's minimum operational range of 600°C and ends after both the laser has been shut off and the temperature has dropped below 600°C. This range of time is dependent on when heating actually began, which means that the significant row numbers vary between experiments.

When attempting to plot and extract information from each data file without LaserPlot, some of the extraction is achievable within Excel, but there are a few features which are essentially irreproducible. The calculations of the heating rates in LaserPlot utilize the user-defined time at which the heating curve transitions into the holding curve, which can be accurately viewed and updated fluidly in real time.

Attempting to reproduce the finessing capability in a program like Excel would result in significant time loss, as the program lacks the smooth user interface that comes with such a specifically tailored program. Along those same lines, LaserPlot's aesthetic controls are quickly and easily accessible, where everything that is needed is already available. It's not that other programs would be incapable of producing the plots or running the calculations. LaserPlot was built for this purpose, making the process easier and faster, with consistent output formats.

2.1.3 Functionality

The capabilities of LaserPlot can be broken down into 5 main sections: data loading, plot controls, heating duration determination, cooling and heating rate calculations, and output options. Each of these categories has screenshot-aided instructions detailing their operation in the information tab of the application, specifically within the Levitation Laser tab.

The data loading section is portrayed in an easy-to-follow display and is the first visible item on the Levitation Laser tab. Selecting Browse (Fig. 29) opens a loading window into the user's PC. Selecting the file provides the program with a pathway from which the data will be read. Upon selection of a file, five areas on the page become instantly populated with information from the file: the time variable, the temperature variable, the laser power variable, the "Input Data" section, and the "Levitation Laser Data" section. The time, temperature, and laser power variables are automatically selected, using the time, corrected temperature, and laser power columns from the file format. The "Input Data" section is displayed in the center of

the screen and shows the tabular layout of the data, as it is read directly from the file. The “Levitation Laser Data” section, on a selectable tab to the right of “Input Data”, displays only four columns. The temp, time, and laser power columns reflect the previously selected variables. The remaining column is titled “Laser” and shows the specific instances when the laser was turned on and when it was turned off. These distinctions are necessary for both plot controls and cooling and heating rate calculations.

The plot controls section allows the user the opportunity to determine plot aesthetics and to manually adjust two items which will be part of the tabular output: gas flow and additional notes (Fig. 30). The gas flow is recorded in the Excel file that is being read by LaserPlot, but if the flow rate was adjusted after that point, it will need to be manually adjusted in the labelled text box. The additional notes feature offers the user a text box, which will occupy its own column in the tabular output file and has no character length limit. The editable plot aesthetics are the plot titles, the colors of the laser on and off sections, the visibility of the cooling and heating rate regression equations, and the line thicknesses for each plot. The plot titles are shown in text boxes to the right of their respective plots, as well as at the top of each plot, and will update in real time as they are changed.

The “Laser” column mentioned in the data loading section consisted of a binary determination of whether the laser was turned on or off in each measured instance. This is visible in the temperature vs time plot and will be expanded upon later in this section. The user has color control over both the “On” and “Off” segments, as well as the Laser Power vs Time curve, using a pop-up color palette, which allows

for the full range of hexadecimal colors and transparency selection (Fig. 31). The cooling and heating rate regression equations can be toggled on and off using a checkbox next to their labels. The last of these controls is the thicknesses of the curves in each plot. This input box defaults to a value of 1.5, but it allows for the user to type in desired values or use vertical arrows to incrementally increase or decrease the thickness in steps of 0.5. The thickness feature of the plot only recognizes increments of 0.5, so inputted values beyond that scope are rounded to the nearest acceptable value within the program and a message appears requesting that a valid value be entered, including the two nearest valid values. Even though an invalid entry does not cause an error in the program, the user is alerted that their selected value is not the one represented in the plot.

The next section is also an adjustable control, but does not fall under the realm of an aesthetic. It is a user input marking the transition from the sample heating to being held at temperature. Using a hover functionality, the program identifies and displays the x and y coordinates of the cursor, which would show either both time and temperature or both time and power. This allows the user to locate the specific time at which the experiment transitions from heating toward holding the sample at an intended temperature in the temperature vs time plot. (Fig. 32) This time can then be inputted into the text box on the right, titled as "Input time where heating becomes holding (s)". This value defaults to the time at which the laser turns off. Entering an illogical value does not terminate the program; rather, it shows NA values. If the value is deleted completely, the plot will disappear. This can be remedied with no loss of progress by changing the input to a rational value. This

input box also has an incremental selection tool associated with it, which allows the user to tick up or down by increments of 0.1°C . Coupling this option with the R^2 value of the heating rate's linear regression allows for optimization of this equation's fit to the data's heating rate.

The calculation of the heating and cooling rates is achieved by two separate methods, both of which are visible in the application and are included in the tabular output file. The first method is linear regression. For a majority of the levitation experiments, the heating rate was either manually kept as constant as possible or a predetermined intended heat rate was selected within the PID settings before the experiment began. This means that the heat rate for a majority of cases should be generally linear in nature. The cooling rate is largely linear in nature as well, though it does decrease with time to a variable degree. The linear regression model shows the best fit line within the data segment, reflecting the greatest R^2 value which explains the highest percentage of the data variability. The second method is an averaging of derivatives. These calculations are based on the exact same time range as the linear model, but the rate at every instance is taken into account.

After optimizing the linear regression model for the heat rate and adjusting the aesthetic controls, there are three different output buttons: the temperature vs time plot, the laser power vs time plot, and a table. Each of these can be downloaded by selecting "Download Temp vs Time Plot", "Download Power vs Time Plot", and "Download Table", respectively. (Fig. 33) The plots can be saved as either PDF or PNG file types. If the file is in a PDF format, every feature of the plot is editable. This means that everything acts as individual objects and can be moved, deleted, or text

font types, colors, and sizes can be changed freely. On the other hand, if all the plot aesthetics and positioning are as desired, downloading a static PNG image allows for easy placement within a document or publication.

The output data table (Table 8) is a single row of data for the plot, covering sixteen different variables that have either been calculated within the program, pulled from the original file loaded into the program, or were generated by the user in the “Additional Notes” or “Gas Flow” input boxes. The calculated variables include the heating duration, the holding duration, the mean holding temperature, the peak temperature, the heating and cooling rates determined by linear regression, and the heating and cooling rates determined by averaged derivative. The heating duration represents the time between where the sample temperature exceeds 600°C and the user-defined point at which the heating curve transitions into holding. From this point and continuing until the laser is turned off represents the holding duration. The mean holding temperature is the average temperature calculated during this time span and the peak temperature is the maximum temperature value recorded during the entire levitation experiment. The variables that were taken from the original file include the sample name, the date of the experiment and the time that the recording began, the composition and relative percentage of Gas A, the composition and relative percentage of Gas B, and the gas flow. The gas flow variable is listed as being taken from the original file and as a user-generated input value. The reason is that the file records the gas flow setting in place when the recording log initiates, but if the gas flow is adjusted during the course of the

experiment, it is not reflected in the log. If there are changes during levitation, the user's input will overwrite the initially recorded value.

2.1.4 Summary and Limitations

The Shiny web application LaserPlot uses the data output from the aerodynamic levitation laser furnace to produce two bivariate plots of temperature vs time and laser power vs time and a table. The plot aesthetics can be adjusted in the application, including coloring, line thicknesses, and the presence of linear regressions and their equations. As the plots can ultimately be downloaded as PDF files, text type, size, color, and location can be further adjusted in editing software applications. The table output downloads as a CSV file, and is populated by machine conditions pulled from the data file, user inputs in the application, and calculations of heating rate, cooling rate, maximum temperature, and mean holding temperature. LaserPlot contains everything necessary to provide a fast, fluid, and easy-to-use data analysis experience.

The program does have certain conditions which must be met in order to function properly. These relate to characteristics of the actual levitation experiment. Based on how the program interprets the data in order to run the various calculations, the following two conditions must be met: the file must represent a single levitation experiment and the laser power must be shut off before recording of the data file ceases.

For the first condition, this means that after the experiment has been completed and the laser has been shut off, the recording must also stop, preserving the single

experiment in the data file. If, rather than ceasing recording at this point, another levitation experiment were to begin in the same file, the program would interpret the entire duration of time until the laser was shut off for the last time as a single run. This means that everything in between the first heating and the last cooling would be recognized by LaserPlot as a single experiment. The calculations for the first heating rate and the last cooling rate would still be accurate, but everything in between would be compromised.

For the second condition, this means that the last row in the data file must have a laser power value of zero. This is necessary because of the manner in which the laser “on” and “off” portions of the curve are recognized by LaserPlot. The “on” portion is determined as the range of values from when the temperature rises above 600°C, which is the minimum pyrometer reading temperature, until the last row where the laser power does not equal zero. The “off” portion is then determined by the difference between the last row of data in the file and the last row where the laser power does not equal 0. If these two values are the same, and the laser “off” portion effectively becomes null, then the program identifies it as a missing variable and cannot function.

With the two requisite conditions for LaserPlot’s functioning obeyed, this tool contains everything necessary to analyze the aerodynamic levitation laser furnace output in a straightforward and fast manner. The computation of several key variables, the allocation of variables from the loaded file, and the option to input additional information offers a seamless compilation of information. Coupled with

the tidy analysis collection, the plot outputs are both of a publication quality and able to be further customized as PDF files with any editing software options.

2.2 RockR

2.2.1 Introduction and Motivation

RockR is a web application, designed to act as a tool for classroom and lab environments. It was created with the intent to provide plotting capabilities wrapped within an easy-to-use user interface. It came about at the request of one of the professors in a collaborative venture between three R-savvy geology master's students: myself, John Shukle, and Jeremiah Mickey. The initial request was for an application that could provide the functionality to create ternary plots, which are triangular plots comprised of three separate axes, each of which is driven by its own variable. Building such a program in R offered the potential and the opportunity to include much more functionality than merely creating ternary plots, which could improve upon plotting capabilities and ease of plotting. It was at this point that the application began to grow and evolve.

RockR's design was educationally-driven, providing the user with instruction, links to relevant literature, and geoscientific examples spliced into the application itself. The provided instruction includes descriptions of how to navigate and operate the various sections of RockR. But it also includes overviews of the different plot types, along with the original papers with which they are associated, and even an interactive model illustrating the mechanics of point location calculations using ternary diagrams. Explanations of how to best organize and format datasets prior to

loading them into the application are also included, using both written and visual descriptions, as well as a link to an R-focused publication on “tidy data” (Wickham, 2014).

While RockR has the capability of plotting data onto blank ternary and bivariate plots, it goes beyond that to include underlying diagrams from which data patterns and relationships can be drawn. Within the geosciences, there are numerous discrimination and classification diagrams utilized in conjunction with data from rocks, minerals, and soils, in addition to numerous other applications (Figs. 34 and 35). However, despite the commonality and frequency with which these plots are used, at this point in time there was not a readily available, easily accessible, and free method by which they could be generated. Some programs do exist, but they either have user costs or require downloading and installation in the form of software packages. RockR aimed to specifically fit the niche of an easy to use and free tool. Perhaps its greatest advantage over other programs is its accessibility. Rather than the alternatives, RockR does not require installation of any kind, as it runs in any browser window. It does not expect programming knowledge or any awareness of coding languages. Even so, the full source code can be viewed via the hyperlink in Appendix B. The web application has streamlined functionality, which provides a fast and fluid experience that can be accessed from any device with browser capabilities (e.g. PC, laptop, tablet, mobile device), and is not operating system dependent.

2.2.2 Functionality

The home page opens to a brief introduction, with an overview of the application layout and organization. The middle portion of the home page contains a detailed table with pictures describing the various discrimination and classification diagrams as well as the additional curves in the metamorphic facies section. The last portion of the home page is the credits information, which includes app authors, RockR presence on various social media outlets, the preferred method of citing the app, a link to the GNU General Public License v3.0 under which the application is licensed, and citations from the various R packages as well as the primary literature references connected via hyperlinks and used as the base for discrimination and classification diagrams.

The resources page contains useful links for data acquisition, American societies, additional resources, and open source publications. Within each of these categories, there are labeled images that hyperlink to the source material. Every one of the websites shown is free to use and contain information useful to both students and professionals.

As the name would suggest, the help page offers additional information concerning data loading and plot creation, with stepwise instructions and screenshots highlighting certain features of the program. At the top of the opening page, sample files can be downloaded for each of the plot types. As the purpose of the application is to streamline and enhance plotting efficiency, it is an open-source project. As a result, the help page also offers a link to the application's GitHub page. This page includes everything that exists in RockR, and can be downloaded directly

or, if the user has their own GitHub account, they can fork the entire repository. Once the files have been downloaded, the entire application could be run locally through RStudio. This also means that, if desired, anyone could take the code and alter it to their own purposes, as long as they adhered to the GNU General Public License v3.0 agreement.

Beyond the home and help pages, the application is broken into three primary sections: the bivariate section, the ternary section, and the metamorphic facies section. The organizational scheme within each section is the same, insofar as the different tabs used to navigate around the section. They each open to a background information page, which outlines the general purpose and highlights original authors and useful publications. The other tab options are the input data page and the create plot page, both of which have some generic similarities present in all the primary sections and some unique characteristics. The input data page consists of functionality facilitating the loading of data files and selection of variables, and the create plot page displays the respective plots with varied aesthetic and functional options.

2.2.3 Teaching tool

The different plot sections open to basic explanations, as well as example diagrams produced using RockR. Within the explanation are links to original publications and author information, offering further background for students. Ternaries are not intrinsically understood conceptual plots, so the ternary section offers multiple avenues by which the user can achieve a more thorough

understanding of the plot purpose and capabilities. As opposed to bivariate diagrams with two axes, with which most people are familiar, ternary diagrams have three different axes. As written explanations are not the optimal method of learning for every student, there is an interactive ternary example within the ternary section. Further along, figure and text combinations detail how to read and interpret these diagrams. And finally, a series of basic equations show how data are normalized, so that each variable is shown relative to the summation of all three variables. The concepts of deciphering plots and normalizing data points are brought together in an interactive ternary diagram (Fig. 36). The input boxes to the left can be adjusted by the user and, as changes are made, the equations next to the input boxes and the ternary diagram both update in real time. This enhances conceptual understanding through the visualization of the effective relationship between the equation and the plotted point. As ternary diagrams are more difficult to understand than bivariate diagrams, it is the most involved information page between the different plot type sections. Within the information sections of the individual plot types, RockR offers hyperlink access to useful and freely accessible resources, which can help improve conceptual learning.

2.2.4 Ease of use

In addition to offering instruction and external resource links, RockR provides an easily navigable user interface that enables quality plot creation. The application is designed such that the process of loading data, creating plots, and manipulating aesthetic controls is fluid and simple. The final product can be quickly downloaded

in a variety of formats at the click of a button. The data loading step offers simple functionality to assist the user in variable selection and combination, without having to parse through their entire data file. These data are then sent to each plot type ready to go, with no adjustments necessary. When dropped into the ternary plot, the data points are automatically normalized, and the various groups are given distinct colors. The aesthetic alterations update in real time, allowing for fast customization of the plot. Additionally, if a discrimination diagram is selected, the individual polygon regions within the diagram can be colored to highlight patterns in the data. By having a specific and purposeful design, RockR is capable of a streamlined plotting ability, with a clean and professional finish. This application was not designed to be revolutionary or unique in its creation. It is not the first application capable of making these plots, nor does it lay claim to any of the plots, diagrams, or curves contained within it. RockR improves upon the plotting processes which already exist, making them fast, easy to use, and free.

2.2.5 Summary

RockR was designed as a tool for both classroom and laboratory environments. It does not claim ownership of any of the discrimination or classification plots and is entirely open-source. It is intended to help facilitate the fluid and expedient production of publication quality plots, including those that overly specific discrimination and classification diagrams. Moreover, this application offers the user fundamental instruction to the different plot types, as well as hyperlinks to

additional information. While other products do exist that can enable plotting onto these sorts of diagrams, RockR is free and requires no installation of software.

The bivariate section has plotting capabilities and aesthetic controls which can be replicated with a wide variety of software applications. However, the controls for these plot characteristics are more immediately available and streamlined and the plotted data can be correlated with numerous varieties of TAS diagrams from publications as far back as 1979 (Fig. 37). The ternary section optimizes the plotting process, which would otherwise be timely and painstaking. This section also includes the most discrimination diagrams, covering a wealth of possible applications. Lastly, the metamorphic facies section is a more unique section. Having two different interactive pressure and temperature-determined plots, this section allows for the plotting of pathways in the context of the different metamorphic facies. The pathways generally follow either intrusion origins or collision origins, showing burial and heating followed by exhumation or vice versa, respectively. In addition this section has the option to toggle on or off mineral phase boundaries and specific gradients.

Being an open-source project, RockR is continuously evolving and improving, with new diagrams being added as requested. RockR simplifies and improves upon existing plotting capabilities, but it also incorporates underlying discrimination and classification diagrams with the plotted data. With the information about the plotting sections, coupled with the hyperlinks to original papers and the interactive ternary example, RockR is able to wrap together necessary functionality and aesthetic control, while excess adjustment potentials. This allows such a browser

application to function as a very structured and efficient plotting tool for the classroom and laboratory environments.

Figures

Fig. 1. Graph of glass-forming melt strengths, with respect to viscosity and temperature changes (Lucas et al., 2017 – modelled after Angell, 1991).

Fig. 2. Log f_{O_2} vs temperature buffers depicting the stable iron oxidation states in the Fe-Si-O system (Frost, 1991).

Fig. 3. Vertical-tube gas mixing furnace diagram showing platinum wire loop and platinum and graphite crucibles used in glass synthesis experiments (Smythe and Brenan, 2015).

Fig. 4. Aerodynamic levitation laser furnace comprised of: (A) continuous wave CO₂ laser; (B) levitation chamber; (C) gas mixing valve; (D) optical pyrometer; (E) video camera.

Fig. 5. Copper hearth plate with concave depressions situated in laser hearth chamber of aerodynamic levitation laser furnace. Hearth rods extending to left and right out from hearth plate and through slits of laser hearth.

Fig. 6. Copper hearth plates used in laser hearth during laser fusing process of glass synthesis methodology, producing spheres 0.5 – 3.0 mm in diameter. The concave depressions contain ~4 mg aliquots of MgSiO_3 powder and the curve of the depressions encourages the powder to fuse in a spherical form as it is heated by the laser.

Fig. 7. Levitation chamber situated in aerodynamic levitation laser furnace with aluminum alloy conical nozzle capable of directing concentrated gas flows centered within chamber.

A

B

Fig. 8. Gas mixing valves combine (A) the individual gases and (B) regulate the gas flow rate of the final mixture.

Fig. 9. An integrated Chino IR-CAS near-infrared optical pyrometer measures the sample surface temperature through a window looking into the levitation chamber. The pyrometer readout is sent directly to the laser furnace software, which tracks both the apparent and absolute (corrected) temperatures.

Fig. 10. Point Grey digital video camera adjusts contrast in order to maintain visibility of molten samples giving off extreme light emissions, which would be dangerous to view with the naked eye.

Fig. 11. Simplified layout for the levitation chamber of the aerodynamic levitation laser furnace. (A) The sealed levitation chamber keep external gases or contaminants from affecting the sample. (B) A conical nozzle with an aperture diameter of either 0.7 mm or 1.0 mm and orifice angles of either 60° or 90°, within which the spherical sample levitates. (C) A single gas flow, which is either a single gas composition or a set ratio of 2 compositions, passes vertically through the conical nozzle. As the flow passes around the sample, it acts upon it and both contains and suspends it. (D) The pyrometer measures the sample temperature by its light emissions, viewed through a glass lens. (E) A 400 W continuous wave CO₂ laser beam is directed at the sample from directly above it (Edited from University of Bristol, UK, Physics Department).

Fig. 12. Sample levitating in conical nozzle and being heated by continuous wave CO₂ laser. The three individual images show snapshots of the same sample taken seconds apart at different temperatures. (A) Heated sample at temperatures approaching liquidus. (B) Sample at temperature above liquidus. (C) Supercooled and vitreous sample (Briggs, 2018).

Fig. 13. Polytetrafluoroethylene washers adhered to double-sided carbon tape in an aluminum dish. Two mm-sized glass spheres are held in place by the carbon tape, positioned within the bounds of the washers prior to the addition of the temporary epoxy.

Fig. 14. Forsterite partially vitrified samples exhibiting "crumpled" exterior.
(A) Sample 10.6.17.6. (B) Sample 10.6.17.8.

Fig. 15. XRD Vantec graphical output of Mg_2SiO_4 (forsterite) sample 10.6.17.6, showing crystalline Bragg's peak within an otherwise amorphous structure.

Fig. 16. XRD LynxEye graphical output of Mg_2SiO_4 (forsterite) sample 10.6.17.20, showing an amorphous structure with a complete lack of crystalline Bragg's peaks.

Fig. 17. SEM EDS spot analysis locations as shown on BSE images of polished forsterite glass sample.

Fig. 18. Dual polished 1.1 mm diameter glass sample with Mg-Fe pyroxene composition. Sample has coarse-grind on base plane and 0.25 μ m polish on top plane.

Fig. 19. Aluminum alloy conical nozzles used in levitation chamber of aerodynamic levitation laser furnace. (A) 90° / 0.7 mm nozzle; (B) 90° / 1.0 mm nozzle; (C) 60° / 0.7 mm nozzle.

Fig. 20. SEM BSE image of polished forsterite glass sample with internal shrinkage void (bubble).

Fig. 21. Graph showing experimental MgO vs SiO₂ weight percentages of forsterite SEM EDS spot analyses relative to the theoretical forsterite weight percentages (TARGET).

Fig. 22. Graph showing experimental MgO vs SiO₂ weight percentages of enstatite SEM EDS spot analyses relative to the theoretical enstatite weight percentages (TARGET).

Fig. 23. Ternary diagram representing SEM multiple spot analyses for 7 $(\text{Mg}_{0.95}\text{Fe}_{0.05})\text{SiO}_3$ pyroxene samples compared against the target intended weight % (En95). For sample levitation conditions: (**circle**) 100% O₂; (**square**) 100% Ar; (**diamond**) 100% 5% CO in Ar; (**triangle**) 100% 5% CO₂ in Ar; (**square with crosshairs**) 50% Ar + 50% O₂.

Fig. 24. Ternary diagram representing SEM multiple spot analyses for 2 $(\text{Mg}_{0.9}\text{Fe}_{0.1})\text{SiO}_3$ pyroxene samples compared against the target intended weight % (En90). Both samples levitated in 100% O_2 .

Fig. 25. Ternary diagram representing EPMA multiple spot analyses for 3 (Mg_{0.9}Fe_{0.1})SiO₃ pyroxene samples, compared against the target intended weight %.

Fig. 26. Ternary diagram representing EPMA multiple spot analyses for 6 $(\text{Mg}_{0.95}\text{Fe}_{0.05})(\text{Si}_{0.95}\text{Fe}_{0.05})\text{O}_3$ pyroxene samples, compared against the target intended weight %.

Fig. 27. The same En95 samples from Fig. 23, after vitrification, used in fugacity-constrained experiments: (A) 3.28.18.1 (Pure Ar); (B) 3.28.18.2 (Pure Ar); (C) 3.28.18.3 (Pure O₂); (D) 3.28.18.4 (Pure O₂); (E) 3.28.18.5 (Pure O₂); (F) 3.28.18.6 (Pure 5% CO₂ in Ar); (G) 3.28.18.7 (Pure 5% CO₂ in Ar); (H) 3.28.18.8 (50/50 O₂ and Ar); (I) 3.28.18.9 (50/50 O₂ and Ar); (J) 3.28.18.10 (Pure 5% CO in Ar); (K) 3.28.18.11 (Pure 5% CO in Ar); (L) 3.28.18.12 (50/50 5% CO in Ar and 5% CO₂ in Ar); (M) 3.28.18.13 (50/50 5% CO in Ar and 5% CO₂ in Ar). Image sizes do not reflect sample diameters, which can be found in Table 2.

Glass Variables

Fig. 28. Pairs plot of synthetic glasses variables, where each variable is plotted against every other variable. The variables shown from upper left to lower right are: sample diameter and the cooling rate, gas flow rate, and peak temperature reached during vitrification. The variable present in a given row represents the Y-axis and the variable present in a given column represents the X-axis.

Sample Gas Flow (CC/minute):
521
Input Gas Flow if it Changed After Turning the Laser On:

Info
Additional Notes:

Fig. 30. Screenshot of plot controls taken from LaserPlot Plot tab and highlighting gas flow and additional notes.

Fig. 31. Screenshot of plot controls taken from LaserPlot Plot tab and highlighting location where plot aesthetics can be controlled for both the temperature vs time and laser power vs time plots. Linear regressions for the heating and cooling rates can be toggled on/off here.

Input time where heating becomes holding (s):
64.596

Sample Heating Rate (Degrees C/second):
20.47708

Sample Cooling Rate (Degrees C/second):
173.3645

Sample Mean Holding Temperature (Degrees C):
This will show as 'NaN' if the heating/holding input time is greater than the
time when the laser power shuts off
1491.188

Fig. 32. Screenshot of plot controls taken from LaserPlot Plot tab and highlighting heat/hold time, which identifies the time that the sample temperature is no longer heating, but rather has begun holding at temperature. This point is necessary to calculate the heating rate, the holding temperature, and the holding duration.

Fig. 33. Screenshot of plot controls taken from LaserPlot Plot tab and highlighting the download options, which includes the choice of plot output format (PNG or PDF), and the buttons for downloading the temperature vs time plot, the laser power vs time plot, and the table of data pulled from the loaded file and calculated by LaserPlot.

Shepard Sediment Classification

Fig. 34. Shepard sediment classification ternary discrimination diagram (Shepard, 1954) using example data points to highlight aesthetic controls. Plot was built in and downloaded from RockR!.

Fig. 35. Total Alkali vs Silica (TAS) (LeBas, 1986) bivariate discrimination diagram showing aesthetic control varieties using Andes example data set. Plot was built in and downloaded from RockR!.

Interactive Ternary Diagram

Change the values below to see how a point shifts on the ternary diagram.

Value 'A'

Normalizes as $\rightarrow 100 \cdot [A / \text{Sum}(A,B,C)] \rightarrow 100 \cdot [1 / 4] = 25 \%$

Value 'B'

Normalizes as $\rightarrow 100 \cdot [B / \text{Sum}(A,B,C)] \rightarrow 100 \cdot [2 / 4] = 50 \%$

Value 'C'

Normalizes as $\rightarrow 100 \cdot [C / \text{Sum}(A,B,C)] \rightarrow 100 \cdot [1 / 4] = 25 \%$

Sum = 4

Fig. 36. Interactive ternary diagram, helping users visualize the calculation of normalized points on a ternary diagram. Changes to the endmember value is reflected in the plot to the right in real time, highlighting the relative portions in a three-axis system.

Fig. 37. Total Alkali vs Silica (TAS) (Cox, 1979) bivariate discrimination diagram built in and downloaded from RockR.

|----------|--|
| Jun 2019 | Indiana University, College of Arts and Sciences,
Indianapolis, IN
Master of Science in Geology, GPA 4.0/4.0
Thesis: Developing Levitation Laser-Fused
Glasses as Proxies for Lower Mantle
Experiments: A Methodological Approach |
| Dec 2018 | Indiana University, College of Arts and Sciences,
Indianapolis, IN
Bachelor of Science in Geology, GPA 3.5/4.0 |
| May 2010 | Indiana University, College of Arts and Sciences,
Bloomington, IN
Bachelor of Arts in Anthropology, GPA 3.4/4.0 |

Experience

Geology Research and Teaching Experience

Graduate Research Assistant - IUPUI May 2017-Apr 2019

- Utilized embedded class IV CO₂ laser within aerodynamic levitation laser furnace under various conditions to create silicate glasses
- Created new procedures with various glass sample mixing, grinding, and polishing techniques
- Coded 2 new applications in R to improve data analysis and teaching capability

Graduate Teaching Assistant - IUPUI Aug 2017-Dec 2017

- Instructed and assisted undergraduate students in optical spectroscopy and hand sample mineral identification techniques
- Prepared lab exercises and graded student homework/laboratory assignments
- Organized, cataloged, and detailed descriptions for approximately 400 mineral and rock thin section samples

Lab Assistant - IUPUI Sep 2015-Mar 2016

- Performed hydroxide treatments of soil samples from lake sediment cores to remove carbon
- Operated centrifuge and isolated samples after acid and base treatments

Archaeological Experience

Archaeological Tech. - Alpine Archaeological Consultants, Inc. July 2012-Oct 2014

- Collaborated in teams of 3-5 people in sagebrush, desert, and alluvial conditions in Colorado, North Dakota, South Dakota, and Wyoming during summer to late fall seasons
- Completed pedestrian surveys of proposed pipeline transects and tracked GPS locations via Trimble unit
- Excavated auger tests, shovel tests, and archaic features including a basin house, hearths, and storage pits
- Profiled, photographed, and mapped feature profile bisects and plan views
- Determined Munsell values and textures of soils present in different levels of units and shovel tests

Crew Chief - Illinois State Archaeological Survey

Sept 2011-June 2012

- Instructed new archaeologists in current company procedures and methodology
- Determined Munsell values and textures of soils present in specific zones
- Scribed feature limits in plan view and zone distinctions in profile view
- Compiled, reviewed, and prepared paperwork for digitizing for a field crew of 70 individuals
- Maintained and operated GPS total station to attain coordinates of mapping nails

Archaeological Tech. - Illinois State Archaeological Survey

May 2010-Sept 2011

- Excavated Terminal Late Woodland and Early Mississippian Period features at a Phase III site in East St. Louis for the New Mississippi River Bridge project
- Processed faunal, floral, ceramic, and lithic cultural material recovered during excavation
- Consulted osteology/bioarchaeology experts regarding human remains

Archaeological Technician - Indiana University

Aug 2009-May 2010

- Managed excavation of multiple shovel tests with volunteers at paleo site outside of Louisville, KY
- Washed, sorted, and cataloged artifacts from 5 sites in southern Indiana

Skills

Computer Software:

- Proficient use of Microsoft Word, Excel, and PowerPoint
- Proficient use of Adobe Illustrator and Acrobat
- Familiar with ArcGIS Desktop and ArcGIS Pro

Equipment Operation:

- Scanning Electron Microscope (SEM)
- Aerodynamic Levitation Laser Furnace
- X-Ray Diffractor (XRD)

Programming Languages:

- Proficient in R and Shiny
- Familiar with HTML and CSS

Professional Affiliations

- Geological Society of America
